## Lesley J. Rogers

Gisela Kaplan

School of Science and Technology, University of New England, Armidale, NSW, Australia

### Early Life and Educational Background of Professor Lesley J. Rogers BSc (Hons), DPhil, DSc, FAA

Lesley J. Rogers was born in Brisbane, Australia, in 1943 and grew up in the outskirts of Adelaide, South Australia. From very early, she was fascinated by animals, both pets and wild animals then abundant in the bushland and creeks where she lived.

On completion of her schooling, she won a Bursary and Commonwealth Scholarship to the University of Adelaide. Initially, she planned to major in physics, but after experiencing the constant displays of overtly negative and sexist behaviour of male staff and predominantly male students in that field, she shifted her attention to the study of animal biology, published her first scientific paper (Rogers 1966) and graduated with first-class honours in Zoology (1964). Her outstanding results won her a scholarship and teaching fellowship to continue her studies at postgraduate level at Harvard University, USA, which she took up the following year. That was at the height of the protests against the Vietnam War in the mid-1960s. She had already been involved in anti-war activities in Adelaide and continuing them in Boston led to her being forced to leave Harvard University after 18 months of study. Although her stay in the USA was under threat, she managed to stay on for a further year working as a research assistant to Professor Marshall M. Kaplan on the isoenzymes of alkaline phosphatase, finding a method to separate plasma isoenzymes generated by the liver versus bone and hence to an easy and accurate diagnosis of liver and bone disorders (Kaplan and Rogers 1969).

In 1968, she moved to London, where she taught science to secondary school students before commencing study for a Doctor of

Philosophy at Sussex University and simultaneously tutoring physics and chemistry to students at the newly established Open University. Under the tutelage of Professor Richard Andrew at Sussex University, she followed her life-long interest in animal behaviour (ethology) and was awarded a Doctor of Philosophy degree in 1971 for research on attentional effects of testosterone on domestic chicks (Andrew and Rogers 1972).

## Professional Career

In 1972, Lesley returned to Australia to take up an academic position in the physiology department at Monash University in Melbourne. There, she conducted research in the laboratory of Richard Mark on the biological correlates of learning and memory. When Richard Mark moved to take up a professorial position at the Australian National University, Canberra, she joined him at the ANU as a senior research fellow in behavioural biology to complete a number of projects.

It was during this time that she made the breakthrough discovery of asymmetry of visual processing in the avian brain; viz., the left hemisphere dominates the ability of the animal to learn a visual discrimination task, whereas the right hemisphere controls aggressive and sexual behaviour (Rogers and Anson 1979).

On returning to Monash University, in the pharmacology department, she continued investigation of lateralized brain function and made her second landmark discovery that development of lateralization in the chicken depends on light exposure of the embryo before hatching: visual stimulation during a critical stage of ontogenesis establishes asymmetry of visual processing. Rogers thus became a leading scholar who discovered asymmetry in the non-human brain and overturned the previously held view that brain asymmetry is determined entirely by genetic processes (as acknowledged and discussed by Güntürkün et al. 2020).

Appointed in 1985 as a lecturer in the physiology department at the University of New England, Armidale, NSW, and following the award of a Doctor of Science from Sussex University in

1987, she rose through the ranks to a personal chair in 1993.

In 2000, she became an elected fellow of the Australian Academy of Science as one of the internationally significant figures in Australian science. On retirement in 2007, she was the first woman at her university to be appointed as emeritus professor.

Her main research collaborators have been professors Richard Andrew at Sussex University, the United Kingdom; Giorgio Vallortigara at the University of Trento, Italy; and Gisela Kaplan at the University of New England, Australia. As of 2020, she has published 233 peer-reviewed papers, 52 book chapters, 12 authored or co-authored books, 7 edited books and 6 special volumes of journals. She continues to conduct research and publish her findings.

## Research Contributions

On returning to Australia in the 1970s and joining the research group of Professor Richard Mark at Monash University, Rogers conducted research on the biological correlates of learning and memory. Using different inhibitors of neural function, it was shown that short- and long-term memory depend on separate cellular processes. One part of this research discovered that long-lasting effects on learning could be caused by brief inhibition of brain protein synthesis in young chicks (Rogers and Drennen 1978). This emerged as a tool for investigating functional differences of the left and right sides of the chick brain.

At that time, asymmetry, or lateralization, of the brain was thought to be a unique characteristic of the human species, a specialization separating us from all other species. Rogers made a breakthrough discovery of asymmetry of visual processing in the avian brain. Disruption of the chick's ability to learn to find grains of food scattered amongst pebbles was caused by treatment of the left hemisphere with cycloheximide, but it did not occur after the same treatment of the right hemisphere (Rogers and Anson 1979). Treatment of the left hemisphere, she found, intercepted biological processes of development

in the first week of life after hatching, and it was followed by short period of susceptibility of the right hemisphere. Thus, it was found that each hemisphere develops at a different rate and each assumes a different way of processing visual information. This asymmetry can be revealed simply by testing a bird with a patch over one eye and then comparing the effect on behaviour with that occurring when the patch is on the other eye.

The next significant step in Rogers' research was the discovery that asymmetry of visual behaviour develops only if the embryo in the egg is exposed to light during a critical period just before hatching. No visual asymmetry develops if the eggs are incubated in the dark (Rogers 1982). The reason for this is that the embryo is oriented inside the egg so that only its right eye can be stimulated by light. Rogers was able to reverse the direction of asymmetry by opening the egg just before hatching, occluding the embryo's right eye and allowing only the left eye to be stimulated by light (Rogers 1990). The behavioural differences between chicks using their left versus right eye were traced to asymmetry of one of the visual pathways in the brain (Rogers and Sink 1988). Hence, brain and behavioural asymmetry, she showed, can be generated and modulated by sensory stimulation in early life. This discovery overthrew another belief about brain lateralization, viz. that it is fixed by expression of the genes alone.

The discovery of asymmetry in the avian brain led to research on lateralization in other species, and in Rogers' laboratory at the University of New England, this included amphibians, marsupials and mammals (summarized by Rogers et al. 2013b). The latter also included research on hand preferences in orangutans conducted with Gisela Kaplan (Rogers and Kaplan 1996) and a series of studies on lateralization in common marmosets (e.g. Cameron and Rogers 1999; Hook and Rogers 2000). In collaboration with Kaplan and students, lateralized visual behaviour was also shown in other avian species, especially the Australian magpie (e.g. Koboroff et al. 2008).

In collaboration with Giorgio Vallortigara at the University of Trento, Italy, Rogers has considered the advantages and disadvantages of having a

lateralized brain (Vallortigara and Rogers 2005). Together with their students, they showed empirically that lateralized chicks have a clear advantage over non-lateralized chicks when they have to use each hemisphere simultaneously to process different information, viz. the left hemisphere to search for food and the right to detect a predator (Rogers et al. 2004). Furthermore, by comparing lateralized behaviour of social and solitary species of bee, they showed that a bias for lateralization to be aligned in a population depends on whether a particular behaviour involves social interaction (Rogers et al. 2013a, 2016).

In both dogs and primates, Rogers and students demonstrated that hand/forepaw preference, as a reflection of which hemisphere is in control, is associated with cognitive bias, exploration behaviour and stress responses (e.g. Gordon and Rogers 2015). Recognition of this led to considering the interface between lateralization, cognition and welfare of animals (e.g. Rogers 2010; Rogers and Kaplan 2019).

## Levallois Technique

Stephen J. Lycett<sup>1</sup> and Metin I. Eren<sup>2</sup>

<sup>1</sup>Department of Anthropology, University at Buffalo, Amherst, NY, USA

<sup>2</sup>Department of Anthropology, Kent State University, Kent, OH, USA

The term “Levallois technique” refers to a strategy of stone tool production, specifically a means of taking a block of stone (core) and producing sharp-edged flake tools through percussive application of a stone hammer. This particular strategy is based around the production and organization of a specific “prepared-core” form (sometimes referred to as “tortoise” or “turtle-backed” cores). This strategic approach to core organization and flake production contrasts with simpler (migrating platform) reduction techniques, which involve simply rotating the core and selecting suitable striking positions on a more ad hoc basis. Stone-tool industries manufactured by these strategies begin to appear broadly simultaneously in both East Africa and Europe around 300,000 years ago (Tryon and Faith 2013), suggestive of convergent technological developments in these different regions (Adler et al. 2014). As with much of the terminology surrounding description of Palaeolithic stone tools, the term “Levallois” is derived from France and refers to the suburb of Paris where such industries were discovered in the late 1800s (Bar-Yosef and Dibble 1995). Following their initial appearance, stone-tool assemblages that include a Levallois component are known from sites across Africa, Europe, and Asia, although they appear to have been less commonly used in East Asia compared with other regions.

The appearance of Levallois industries during the latter half of the Middle Pleistocene has

contributed to an enduring interest in these industries among archaeologists. Based on their chronology and their geographic distribution, the use of the Levallois technique has an association with both Neanderthal populations (*Homo neanderthalensis*) and early modern humans (*Homo sapiens*). This associates the emergence of Levallois industries with a key phase in human evolution, when relative brain sizes were approaching the modern human range, and the point at which our own species was emerging (Hublin 2009). These factors – as well as the implication that these industries represent an organized and strategic approach to predetermined stone flake production – has contributed to the role these artifacts have also played in discussions surrounding the evolution of cognitive abilities, planning strategies, learning strategies, and linguistic capabilities during the latest phases of human evolution (Schlanger 1996; Lycett and Eren 2013). By no means is there agreement among archaeologists on several of these matters, and a diversity of opinions can be seen in the literature surrounding these industries.

Levallois-style industries began to draw academic attention during the late 1800s (for historical reviews see Bar-Yosef and Dibble 1995; Lycett and Eren 2013). Spurrell, an archaeologist who described a series of sites in southeast England in 1884, for example, referred to the geometric configuration of domed cores he was observing, the specific use of “prepared” surfaces, and the production of large “knife-like” and “turtle-backed” flakes from these specially prepared cores (see Lycett and Eren 2013 for discussion and further references relating to this history). This emphasized the idea that specific core forms were being produced in order to procure flakes that removed a large portion of the core’s specially prepared surface. During the early part of the nineteenth century, scholars in France and the United Kingdom repeated many of these sentiments, setting much of the tone of discussion relating to Levallois industries over the subsequent years. In the 1950s, the famous French archaeologist François Bordes lay down what may be the quintessential definition of Levallois as a means of producing large flake(s) “predetermined

by special preparation prior to its detachment from the core” (translation from Schlanger 1996: 231). Paraphrases of this definition can be seen in archaeological and human evolution textbooks to the present day.

Of particular note in discussions of Levallois has been reference to the “Levallois flakes,” or the flakes that are removed from the specially prepared and domed surfaces of the Levallois core. The influence of Bordes in particular led to Levallois industries often being defined and classified on the presence and frequency of these “Levallois” flakes. In some respects, however, this emphasis on flakes resulted in Levallois industries being thought of in archaeological terms, less as a technique or process, but more as an end product or result. By the 1980s, however, disquiet concerning the reliability by which so-called Levallois flakes could be reliably identified was increasingly being stated. These difficulties surrounding the definition and conceptualization of Levallois industries have been referred to as the “Levallois problem” (see Van Peer 1992 for review).

Recognition of the Levallois problem led some to return the issue of technique and process of manufacture as a central concern (Schlanger 1996). Most notably, Boëda (1995) outlined an influential description and definition of Levallois manufacture based around what he referred to as the “volumetric concept.” Boëda’s conceptualization of Levallois production emphasized several points. Among these was the bifacial configuration of the core, consisting of two flaked surfaces that intersected (Fig. 1). One of these surfaces was steeper than the other and may retain remnants of the original rock surface. The other face was extensively flaked, being domed in form. It is from this latter surface that the Levallois flakes were removed through removal of a flake or flakes by means of a blow at an angle broadly parallel to the plane of intersection (i.e., margin) demarcating the core’s two surfaces. Upon removal of these flakes, the core’s domed surface can be reinstated by removing a series of short flakes from around the core’s margin. Thereafter, further Levallois flakes can be removed. It has been shown that several series of these flaking episodes on a single

**Levallois Technique, Fig. 1** Classic sequence of Levallois reduction, showing the removal of a “preferential Levallois flake” (PLF) at the close of each sequence. In the initial phase (left), a nodule is taken and the bifacial configuration of the core is established, consisting of two flaked surfaces that intersect. These surfaces are

hierarchically organized: one being for the preparation of striking platforms, the other being the surface from which PLFs are removed. This latter surface is domed, exhibiting convexity across its surface. Following initial removal of the first PLF, the convexity of the primary surface can be reprepared and further PLFs may be removed

core may have been undertaken by prehistoric peoples (Van Peer 1992; Schlanger 1996).

In recent years, increased attention has been given to the motivating factors potentially underlying the widespread production of Levallois industries. This has included recognition that Levallois reduction may have statistical dimensions of variability that distinguish it from more ad hoc (migrating platform) strategies of production. This includes a demonstration that Levallois cores configured according to Boëda’s (1995) volumetric concepts, can result in an economic means of core reduction while simultaneously maximizing the length of cutting edge removed from the primary flaking surface of the core (Brantingham and Kuhn 2001; Lycett and Eren 2013). Recent discussions have also emphasized that, at a statistical level, the Levallois technique provided prehistoric peoples with a means of producing flakes with strong edge angles and greater potential to be resharpened repeatedly (Eren and Lycett 2016). Current discussions are, therefore, emphasizing a range nonmutually exclusive features that, in combination, may explain why assemblages made through application of the Levallois technique were so widespread during the latter part of the Pleistocene.

## Lexigrams

Alexandria Cairo-Evans  
University of Chicago, Chicago, IL, USA

## Synonyms

[Lexigraph](#)

## Definition

A lexigram is a single symbol that graphically represents a single word or concept. A collection of lexigrams makes up a lexigraphy, a logographic writing system in which English words are represented by pictures or symbols. Lexigrams are designed to be unequivocal, with meanings semantically and syntactically unambiguous.

## Introduction

The lexigram as a word-symbol was developed in tandem with artificial language consisting of the first set of lexigrams, named “Yerkish” in honor of Dr. Robert M. Yerkes and Yerkes National Primate Research Center (“Yerkes”) at Emory University in Atlanta, Georgia, where lexigrams were first used (Rumbaugh et al. 1973; von Glasersfeld 1974).

Lexigrams were developed for the purposes of exploring the capacity for language in great apes and have been used extensively in chimpanzee (*Pan troglodytes*) and bonobo (*Pan paniscus*) communication research, notably including Kanzi, arguably the most proficient nonhuman primate language user (Lloyd 2004). Since the inception of lexigrams as analogues for English, use has expanded beyond great ape language research to include communication research in other animals such as the domestic dog (*Canis familiaris*, Rossi and Ades 2007). Work with human children indicates arbitrary lexigrams, such as those used in nonhuman communication research, are comparably learnable to iconic images that display visual similarity to referents (Barton et al. 2006). Communication aids using pictures, lexigrams, and other symbols are also used as an instrument to facilitate communication for children and adults with developmental delays and language disabilities. This practice has largely been found to be effective in improving vocabulary comprehension and production (Allen et al. 2017; Lancioni et al. 2007). Lexigrams are an important tool in the work of animal communication researchers, developmental researchers, and language disorder specialists.

## Development

The development of lexigrams was a response to great ape language research. The work of Gardner and Gardner (1969) demonstrated vocabulary acquisition in the chimpanzee, Washoe, and the subsequent work of Gardner and Gardner (1971) and Premack (1971) in visual signs and symbols as a means of communication led Rumbaugh et al. (1973) to question the limits of ape language behaviors and in turn develop a technology primarily for the purposes of objective and efficient investigation into language acquisition and ability.

The first 125 lexigrams were developed at Yerkes as a part of the Language ANAlog (LANA) project, Lana being the first chimpanzee to be trained in the use of lexigrams. The design of these lexigrams, their computerization, and

Yerkish grammar was carried out by von Glasersfeld and Pier Paolo Pisani with three guidelines in mind that can be summarized from von Glasersfeld (1974) as:

1. Design constraint: Visual, single-word symbols able to be represented on single keys and combined to form a keyboard.
2. Unequivocal meaning: Discrete semantic and syntactic meaning with no ambiguity.
3. English Translation: Similar enough to English for word-for-word translations to be understood by English speakers.

### Design Constraint

Rumbaugh et al.'s (1973) design for the original lexigrams adhered to a design code characterized by the presentation of specific design elements that could be superimposed atop one another. Nine single design elements, including lines and shapes, were combined in unique ways to yield 255 symbols (Fig. 1). These symbols were differentiated by eight basic colors. Red, for example, corresponds with ingestible items, such as the lexigram for "food" and "drink," while green indicates parts of the body (Fig. 2). With shared design elements and color-coded features, a simple semantic code was achieved, wherein conceptual categories are indicated by shared symbolic features (von Glasersfeld 1974).

### Unequivocal Meaning

Discussed by Rumbaugh et al. (1973), these initial lexigrams were based upon spoken English language, with specific care taken to eliminate the natural syntactic and semantic ambiguity of words. Each lexigram corresponds to a single meaning of a single English word, and are therefore semantically unambiguous. For example, the lexigram for "stick" always refers to a long, thin, solid, rounded object, such as a small piece of wood from a tree, and never to one object adhered to another, to a "stick" of butter, or any other use of the word.

Strict one-for-one relationships between concepts and lexigrams address semantic ambiguity. Syntactic ambiguity refers to a sentence in which the receiver cannot discern the meaning due to ambiguity regarding role assignment. The

sentence "He put the ketchup on himself" consists of words that are semantically unambiguous, yet syntactic ambiguity results in a listener unsure whether he put the ketchup in his lap or on an appropriate food item all by himself. Eliminating syntactic ambiguity for lexigrams was achieved by using a correlational grammar structure developed previously by von Glasersfeld (1974) in his work with machine translation and automatic language analysis.

The grammar structure of lexigram phrases is correlational due to the way in which lexigrams are linked. Adjacent lexigrams can be thought of as a left-hand (LH) and a right-hand (RH) piece, linked by an implied correlator between them. The initial vocabulary of lexigrams consisted of 35 conceptual classes, with possible RH lexigrams for each LH determined by the characteristics of its class and each class differing from each other. Where English grammar allows the separation of semantics and syntax, lexigram phrases do not. The order of lexigrams defines the grammatical structure, as Rumbaugh et al. (1973) explain regarding the phrase "Lana eats juice." While the use of the English word "eats" is semantically incorrect in referring to "juice," the syntactic validity of the statement remains. This is a phrase that conforms to English grammar. The phrase "Lana eats juice" constructed with lexigrams, however, is neither semantically nor syntactically valid. "Juice" does not belong to a conceptual class that allows the subject to "eat" it, and therefore, the phrase violates the rules of correlational grammar.

The number of lexigrams and grammatical correlators was limited during initial inception, but Rumbaugh et al. (1973) point out the system is open-ended, with no inherent constraints on the possible number of lexigrams that could be incorporated into a language system and no limit to the number of conceptual classes or resulting correlators. With strict adherence to a unitary one-lexigram one-meaning system, a system of lexigrams can be composed of many semantically distinct words, and as a vocabulary that utilizes correlational grammar grows, so too does the number of conceptual classes and correlators that connect these words, without violating the principals of unequivocal semantic and syntactic meaning.

# DESIGN ELEMENTS

# EXAMPLES OF LEXIGRAMS

## English Translation

As lexigrams were developed primarily for use by researchers in exploring communication, the translations between lexigram phrases and their word-for-word English translations are intended to be understood by English speakers. Word meanings have a direct relationship between lexigram and English, but as von Glasersfeld (1974) confers, the grammar employed is

specifically designed to be simple, consistent for the learner, and structurally similar to English in order to aid understanding by the receiver, as evident in the phrase “stick which-is blue dirty.” The phrase in lexigrams does not require adverbs such as “the,” nor linking verbs such as “is.” Despite using different rules of grammar, the direct translation “[the] stick which is blue [is] dirty” is salient for English speakers.

## Semantic Colour-Coding of Lexigrams

| Colour     | General Type                            | Lexigram Classes                               |
|------------|-----------------------------------------|------------------------------------------------|
| violet     | Autonomous Actor                        | AP, AV, AO, AM.                                |
| orange     | Spatial Objects,<br>Spatial Concepts    | FA, FP, TF, CT, WR.                            |
| red        | Ingestibles                             | EU, EM, ED.                                    |
| green      | Parts of Body                           | PB.                                            |
| blue-grey  | States and Conditions                   | ST, LS, CD.                                    |
| blue       | Activities                              | VA, VB, VC, VD, VE, VG,<br>VL, VM, VP, VS, VW. |
| black      | Prepositions, Determiners,<br>particles | DC, DD, DQ, DP, LP, ID,<br>NF, PP.             |
| white (+)  | Affirmation                             | "YES"                                          |
| yellow (+) | Sentential Modifiers                    | Query, Please, Negation,<br>Period.            |

(+) White and yellow are available in the first feedback projector (left) only, where the sentential modifiers appear.

## Animal Language Research

### Kanzi

Born at Yerkes in October 1980, Kanzi, a bonobo, was assigned to the Language Research Center (LRC), at Georgia State University in Atlanta, Georgia, alongside his mother at 6 months old. Lexigram keyboards were typically used at the LRC in accordance with language training

procedures established in part by Rumbaugh et al. (1973), though the lexigram communication system itself differed considerably. Lexigrams used at the LRC did not feature color codes for class or adherence to a correlational grammar (Savage-Rumbaugh et al. 1986).

Kanzi, while present during his mother's training exercises, was never a participant himself. Despite this, Sue Savage-Rumbaugh's team

reportedly observed Kanzi, in his mother's absence, spontaneously use the lexigram keyboard. This use of lexigrams without explicit training and instruction changed the way LRC research with chimpanzees and bonobos was carried out, instead shifting to a language learning model involving more naturalistic methodology. As Savage-Rumbaugh et al. (1986) report, this language-rich environment would consist of both lexigrams and spoken English, with researchers modeling lexigram use concurrently with typical spoken conversation between one another as well as when communicating directly to subjects.

Within the first week of following Kanzi after his mother temporarily left the LRC, he was found to proficiently use eight lexigrams, and over the next 17 months, effectively used 44 different lexigrams in 764 unique combinations (Savage-Rumbaugh et al. 1985). Kanzi's vocabulary has continued to grow, with reportedly high success both using lexigrams and understanding spoken English (Savage-Rumbaugh et al. 1993).

### Sofia

A noteworthy case of lexigram use in non-primate animal research is that of Sofia, a dog born in São Paulo and raised in Rossi's home as a pet (Rossi and Ades 2007). The lexigram keyboard used includes configurations closely resembling the original eight design elements of Rumbaugh et al. (1973), consisting of six distinct configurations of lines and shapes, plus a blank key, and sheet of newsprint. These lexigrams include the English meanings: walk, petting, toy, water, food, crate, and lastly urine, corresponding with the sheet of newsprint. Arranged into a three-dimensional lexigram keyboard, these symbols were used to investigate the production of communicative behavior (Rossi and Ades 2007).

Sofia was able to use these lexigrams in Rossi and Ades' (2007) trials with a significant success rate, with gaze-direction and nondirected action patterns such as nose-licking suggesting both intention and motivation. Lexigrams were shown to be generalizable, with Sofia using a single lexigram to refer to many items within the same category: Toy, for example, was induced by stuffed toys, balls, and a laser pointer. Spontaneously,

Sofia was also able to use lexigrams directed at strangers naïve to the experiment. The study of Sofia's use of lexigrams by Rossi and Ades (2007) was the first of its kind to be conducted with dogs, and speaks to the enduring value of lexigrams in animal communication research.

## Human Augmentative and Alternative Modes of Communication

Systems for aiding communication with children and adults with developmental delays and language disabilities can broadly be referred to as Augmentative and alternative modes of communication (AAC) and include tools such as the Picture Exchange Communication System (PECS) or comparable pictorial systems, and voice output communication aids (VOCAs). PECSs include lexigrams as well as iconographic imagery, and these combined form sets of graphics that are used to facilitate communication as an alternative or augmentation to spoken language. VOCAs are electronic devices that produce verbal messages in response to manual selection of images such as those found in PECSs (Lancioni et al. 2007).

AAC devices, both PECSs and VOCAs, have been studied to determine efficacy in use with persons with developmental disabilities such as autism, clinically severe to profound mental retardation, childhood apraxia of speech, and other complex communication needs. These systems have been found to be successful for the introduction of request-making, vocabulary skill improvement of single words, and improvement in production of multi-symbol expressions (Allen et al. 2017; Lancioni et al. 2007).

## Conclusion

Rooted in the initial designs of the LANA project, lexigrams have changed since their creation as a system of the artificial Yerkish language. Whereas color-coded conceptual classes and correlational grammar were not used by the LRC, the group was instrumental in popularizing use of lexigrams

with headline-making chimpanzees and bonobos. Great ape use of lexigrams persists, as does use in communication research with other animals, including domestic dogs. Lexigrams are also used as a tool to facilitate communication with children and adults with developmental delays and language disabilities.

## Introduction

All living organisms, ranging from archaea and bacteria to fungi, plants, and animals, can be described through their life cycle, which is how and when they grow, mature, reproduce, and die. The description of the life cycle is what we define as the life history of a species. The study of the diversity of life histories allows us to understand the causes and consequences of the variation in life cycles that range from a few hours for some bacteria to a few centuries for some plant species. When it comes to understanding the tremendous diversity of life histories found in nature, two traits become particularly important: survival and fecundity. Indeed, the probability that an organism survives long enough to reproduce (juvenile survival), the probability that it survives long enough to do so repeatedly (adult survival), and the number of offspring produced at each reproductive event (fecundity) add up to determine the total number of offspring produced throughout the lifetime of an organism. Lifetime number of offspring provides an estimate of Darwinian fitness (the genetic contribution of an individual to the next generation's gene pool) and is what natural selection ultimately acts on. Hence, variations in life history, and by extension variations in survival and fecundity, are molded by natural selection and expected to mirror adaptation of populations and species to their environment (Roff 1992; Stearns 1992).

Variations in life history and adaptation to the environment can be classified along a fast–slow

continuum, with high reproductive rate and low survival at one end versus slow reproductive rate and high survival at the other end. Organisms with fast life histories thrive in unpredictable or unstable environments that cause large fluctuations in population growth rates ( $r$ ) and population sizes. Organisms with slow life histories, however, prosper in more stable environments thereby allowing their population sizes to be close to the maximum sustainable size in the given environment or carrying capacity ( $K$ ) (Oli 2004; Saether and Bakke 2000; Salguero-Gómez et al. 2016). In population ecology, fast and slow life histories are thus referred to as  $r$ - and  $K$ -strategies, respectively (MacArthur and Wilson 1967). Organisms with fast life histories include, among others, bacteria, annual plants (grasses), and small mammals (mouse), whereas organisms with slow life histories are well represented by perennial plants (trees) and large mammals (elephants and humans). Yet, most organisms' life history falls somewhere in-between a fast and a slow pace of life.

## Fitness and Life History Trade-Offs

Following the theory of evolution by natural selection, an organism should maximize its Darwinian fitness at any given time. Thus, an organism with highest Darwinian fitness would start reproducing directly after being born, reproduce continuously, produce an infinite number of offspring at each reproductive event, and live indefinitely. The existence of such an organism, the so-called *Darwinian demon*, presumes the absence of any constraints at all. However, all living organisms need energy and time to grow, maintain their bodies, and reproduce. In nature, resources are usually in limited supply, and there is often competition to access them (e.g., food patches for animals, access to sunlight and minerals for plants). When food is unlimited, such as during large migrations of prey species, in mast years of seed production, or under artificial conditions, there are still limitations on how much food an organism can ingest and in how efficiently it transforms energy enclosed in food into cellular

energy, used to fuel its life cycle. Therefore, each organism is expected to have access to limited (non-infinite) resources that must be divided among life history traits such as growth, body maintenance, and reproduction. In addition, all biological, chemical, and physical processes take time to complete and have a specific order in which they need to be realized. Thus, each organism is also expected to be constrained in terms of when and how it should allocate its limited resources among different life history traits. How much energy and time is allocated to one life history trait at the expense of others is what defines a life history trade-off (Stearns 1992). As mentioned above, from an evolutionary perspective, the optimal solution to a life history trade-off is one that maximizes Darwinian fitness. There is, however, rarely a single solution to a given life history trade-off, and multiple solutions, depending on environmental conditions, are possible. As a consequence, solutions to a trade-off can greatly differ among species but also among populations within a species and among individuals within a population (McNamara and Houston 1996). Alternative solutions to a given life history trade-off are defined as alternative life history strategies.

There are a large number of trade-offs that can be defined in the context of energy and time allocation to reproduction and survival. Some of the most important trade-offs that organisms face through their life cycle are (i) how fast and how long to grow before starting to reproduce, (ii) how often to reproduce and how much time and energy to invest in each reproductive attempt, and (iii) how to divide resources between offspring number and size.

### The Trade-Off Between Growth and Reproduction

The trade-off between growth and reproduction determines an organism's size and age at first reproduction. Some stages of the life cycle of organisms, specifically the early stages, are particularly vulnerable to predation. As the probability of dying from predation greatly declines when an organism increases in size, selection should favor individuals with a fast growth during the

life stages most susceptible to predation. Furthermore, when predation remains important throughout the life cycle, selection is also expected to favor individuals that reach sexual maturity quickly and have an early onset of reproduction. Examples of the trade-off between growth and reproduction are found across fish species, where small species like guppies (*Poecilia reticulata*), which mainly feed on invertebrates, use their energy to grow fast and reproduce rapidly, but never attain the size that would give them defense against predators. Larger fish, like the Atlantic bluefin tuna (*Thunnus thynnus*) or the great white shark (*Carcharodon carcharias*), which are opportunistic predators, reach a large size but have a much delayed reproduction. In species that grow continuously throughout their life, selection will select for an optimal size at first reproduction following two conditions: first, fecundity needs to increase with size (e.g., female fish produce more eggs as they grow larger, and trees produce more seeds as they grow bigger); and second, growth rate needs to decrease after reproduction started, due to energy being allocated to both reproduction and growth rather than to growth alone. Age at first reproduction in Atlantic cod (*Gadus morhua*) is a good example of the growth versus reproduction trade-off. A reduction in age at first reproduction of Atlantic cod has been observed with an increase in fishing pressure on larger-sized animals, which removed some of the benefits of growing large before reproducing for the first time (de Roos et al. 2006; Rowell 1993). Similarly, an optimal size at first reproduction is also expected in species that do not grow continuously but where individuals could start to reproduce before completing body growth. In bighorn sheep (*Ovis canadensis*), where females could start to reproduce at 2 years old and grow until 6 years old, age at first reproduction is strongly affected by body size suggesting an optimal size for first reproduction (e.g., Martin and Festa-Bianchet 2012).

### The Trade-Off Between Current Reproduction and Survival

The trade-off between current reproduction and survival posits that the amount of resources

allocated to immediate reproduction at the cost of survival will be justified by the probability of reproductive success. It is therefore expected that the frequency and amount of reproduction are negatively correlated with the longevity of a species. It is easy to think of circumstances under which reproduction could lead to decreases in survival. Reproductive individuals might be more visible (e.g., birds' plumage colors during reproduction, mating displays and calls that attract both mates and predators), more active, slower, or less agile than nonreproductive individuals and thus may suffer higher risk of predation. Higher risk of predation due to reproductive behavior can arise in four different ways. First, predators or parasites may detect mating calls or mating displays such as opossums locating mate calling frogs (Ryan et al. 1981). Second, instead of detecting mating calls, predators might attract prey by mimicking their mating calls. In fireflies, females of the species *Photuris versicolor* attract and predate male of other firefly species by mimicking the mating flashes of other female species (Lloyd 1975; Lloyd and Wing 1983). Third, the increase in activity linked to reproduction might increase an animal's predation risk by either making it more visible or by simply increasing its probability to encounter predators. In tick-tock cicadas (*Cicadetta quadricincta*), mate-seeking males are more frequently captured by web-building spiders than females are (Gwynne 1987). Fourth, defense of young by parents might place a reproductive individuals at higher risk of predation when the predator can prey upon both parents and the offspring. In sticklebacks, males guard and defend the brood against fish predation (Pressley 1981). In addition to an increase in predation-related mortality, reproductive individuals might be exposed to a higher risk of death by disease, if the energy invested in reproduction is diverted from the immune system and physiological maintenance of the organism. Thus, trade-offs between current reproduction and survival are linked to trade-offs between reproduction and body condition, since most of the time a decrease in survival probability after reproduction is due to a decrease in overall body condition. Furthermore, the trade-off between reproduction

and survival is strongly linked to the trade-off between current and future reproduction since an individual must survive in order to reproduce in the future.

### The Trade-Off Between Offspring Quantity and Quality

Once an individual commits to reproducing, given the set amount of energy it can allocate to reproduction, a major trade-off is the trade-off between offspring quantity and quality. This concept considers that offspring survival is dependent on their "quality," e.g., body size. Thus, in order to maximize Darwinian fitness, the limited amount of resources invested in reproduction should be maximized as a function of number of offspring and offspring quality. Should the majority of energy be invested in producing only one sizeable offspring or multiple smaller offspring? When offspring survival is low, two main strategies could arise to maximize the probability of offspring reaching maturity. First, if increasing the size of an offspring increases its survival, then producing fewer, larger offspring would be adequate. However, this is also a risky strategy since only a few offspring are produced. The second strategy to counterbalance low juvenile survival is not to try to increase juvenile survival but simply to produce an extremely large number of offspring, thus leading to a high probability of having some offspring reaching maturity. Orchids are a good example for the strategy of producing large numbers of offspring with minimum energy invested per individual offspring, given that orchids have the smallest seeds of all flowering plants and produce millions of them. An orchid seed has virtually no reserves and relies on symbiotic interactions with a fungus to develop (Kull et al. 2009). On the other hand, flowering plants such as the coco de mer (*Lodoicea maldivica*) produce only a few seeds, but each seed weighs between 15 and 30 kg, allowing them to germinate and grow on really poor-quality soil. The trade-off between number and size of offspring could also be observed within species. A classic model for this trade-off is Lack's clutch size in birds (Lack 1954), which illustrates that there are an optimal number of offspring to produce. The model

stipulates that if the survival probability of an offspring decreases as the number of offspring produced increases, then there are an optimal number of offspring that maximize the number of offspring surviving. The decrease in offspring survival probability with larger clutch size could be due to a decrease in egg size or an increase competition between offspring for parental care.

### **Life History Trade-Offs and the Evolution of Viviparity and Parental Care**

Increasing the size of the egg or the offspring is not the only strategy to maximize the number of surviving offspring. The probability of an offspring surviving until adulthood is an important parameter linked to a number of different trade-offs. Since juvenile survival has a direct impact on Darwinian fitness, strategies to increase early survival are under strong selection. The evolution of different modes of reproduction, from oviparity to ovoviviparity and viviparity, was driven also by life history strategies that allow reducing early juvenile mortality and favoring the production of fewer offspring but of higher quality. Oviparous animal species lay eggs that contain high amount of nutriment and that develop outside the body cavity of their mother. In ovoviviparous species, the embryo is still relying on resources enclosed in the egg for its development, but the eggs are retained inside the female's body cavity until they are ready to hatch. It allows reducing exposure to predation and pathogens during the egg stage. Finally, viviparous species produce very small eggs that have few or no nutrients, the embryo must feed on resources passed on from the mother during development, and thus mothers give birth to live offspring. It allows the production of larger and more mature offspring, further reducing the costs of predation and pathogen exposures. Generally, the same is true for the evolution of any form of parental care that reduces juvenile mortality and permits greater investment in fewer, larger offspring (Clutton-Brock 1991; Royle et al. 2012).

### **Life History Trade-Offs in Semelparous and Iteroparous Reproductive Strategies**

Life history traits, such as fecundity, timing of reproduction, size and number of offspring, and parental care, can be grouped together into general reproductive strategies that are used by multiple species. Semelparity occurs when a species reproduces only once during its lifetime, produces a large number of offspring, and then dies. Semelparity is thus also known as "big bang" reproduction. Semelparous species accumulate resources and use them during a single reproductive event, detrimental to their own condition, to the point that they do not survive. Semelparity is seen in annual plants, in long-lived plants such as agaves, in many species of fish such as salmon, in insects, and in mollusks, but rarely in large vertebrates. Iteroparity describes species that reproduce repeatedly during their lifetime. Some animals are able to mate only once per year but survive through multiple mating seasons. Most perennial plants are iteroparous, as are most mollusks, insects, and vertebrates, including most reptiles as well as virtually all mammals, birds, and most fish. Semelparous and iteroparous strategies are the result of alternative prioritization of life history trade-offs. In semelparous organisms the main trade-off is how much an organism should grow before reproducing, given that size and fecundity are related, whereas in iteroparous organisms, the main trade-off is how much to invest in each reproductive event versus maintenance and survival.

### **Acquisition and Allocation of Resources in Life History Trade-Offs**

While studies of life history trade-offs have been highly successful at illustrating trade-offs comparing multiple species and using a phylogenetic approach, studies of trade-offs within species are often more problematic. Life history trade-offs are, by definition, a compromise in resource allocation. However, not all individuals acquire the

same amount of resources, a notion known as individual heterogeneity in resource acquisition. When among-individual variation in resource acquisition is small relative to the variation in resource allocation to reproduction and survival, then a trade-off between survival and reproduction could be observed (van Noordwijk and de Jong 1986). On the other hand, when variation in energy acquisition is large relative to the variation in energy allocation, a positive correlation between survival and reproduction is observed instead of a trade-off. As an example, when testing for trade-offs between growth and reproduction, there may be no apparent trade-offs if size and resource acquisition covary, and thus larger individuals have more resources than smaller individuals to invest in both growth and reproduction (Reznick et al. 2000). However, once the variation in size or resource acquisition is controlled for, either experimentally or statistically, trade-offs should become apparent (Reznick et al. 2000). Thus, when studying life history trade-offs, it is important to understand and consider the existence of individual heterogeneity (Tettamanti et al. 2015).

The amount of available resources for organisms to acquire and allocate to life history traits frequently varies with environmental conditions in either a predictable or an unpredictable manner. In a variable and predictable environment, being able to adjust resource allocation according to environmental conditions and thus to resource acquisition is key to maximizing Darwinian fitness. The capacity to respond differently to different environmental conditions is referred to as phenotypic plasticity. Phenotypic plasticity in life history traits is observed in a wide range of species. For example, spring temperature is a good predictor of timing of food availability in insectivorous great tits (*Parus major*), and the date on which adults lay their eggs varies as a function of spring temperature. This allows synchronization of the hatching date of individuals' clutches with the date of peak caterpillar abundance, thus optimizing resource availability for offspring growth and fitness (Charmanier et al. 2008).

## Mechanisms of Life History Evolution

For life history traits to evolve, they must have a genetic basis. Hence, our understanding of the evolution of life history trajectories also requires an understanding of the genetic, molecular, and physiological pathways that link the genotype to the phenotype. A main assumption of life history theory is that trade-offs are generated by competitive allocation of resources, with the allocation of limiting resources to one trait having negative consequences for other traits requiring the same resources (Flatt and Heyland 2011; Zera and Harshman 2001). As a consequence, the diversification of life histories is closely linked to all the molecular and physiological activities that regulate the flow of energy through the body of organisms – that is to say their metabolism. Variation in the secretion of hormones with strong effects on the metabolism and on life history trade-offs is thus one of the mechanisms underlying the integration of life history traits. In animals, this includes steroid hormones such as the male hormone testosterone and the stress hormone corticosterone, which both regulate the trade-off between reproduction and survival, and metabolic peptides such as the insulin-like growth hormone that regulates the trade-off between growth and somatic maintenance (Flatt and Heyland 2011; Zera and Harshman 2001). Remarkably, genes encoding for such hormones and their receptors, which match growth and reproduction to nutrient supply, have been found to be evolutionarily conserved in the animal kingdom, ranging from organisms such as the budding yeast (*Saccharomyces cerevisiae*), the nematode worm (*Caenorhabditis elegans*), and the fruit fly (*Drosophila melanogaster*) to humans (Flatt and Heyland 2011). Mechanistic explanations of life history trade-offs do not rely uniquely on competitive resource allocation, and systems such as metabolic waste management can also generate non-resource-based trade-offs. For example, in aerobic organisms, the transduction of energy from food to cellular energy during mitochondrial respiration has, as an inevitable side effect, the production of reactive oxygen species that can

damage the soma as well as reduce organism reproduction and survival (Monaghan et al. 2009). Indeed, when the production of reactive oxygen species outweighs the cellular antioxidant defenses, organisms are exposed to oxidative stress. This stress can mediate life history trade-offs, such as that between reproduction and survival, if the processing of resources allocated to reproduction creates an oxidative debt on survival (Monaghan et al. 2009; Stier et al. 2014).

## Life History and Behaviors

For a long time, animal behaviors have been poorly considered when studying life history and natural selection. However, the emergence of research on animal personalities has led to both the development of new theories and the accumulation of evidence about the importance of behaviors in shaping species' life histories (Réale et al. 2009; Martin et al. 2014). In particular, the existence of feedback loops between behaviors and life histories or morphological traits has been shown to provide an adaptive explanation for the evolution of animal personality and for the development of life histories (Wolf et al. 2007). For example, individuals with high expectations of future reproduction, that have much to lose, should be more risk-averse than individuals with low expectations. In addition, being more risk-averse increases survival probability and thus by definition increases expectations of future reproduction. This creates a positive feedback loop where the behavior and life history strategy are reinforcing each other.

Studies on sexual selection also illustrate important correlation between life history and behaviors with the existence of alternative mating strategies (Réale et al. 2009). Alternative mating strategies are usually defined by alternative mating behaviors, allowing the emergence of alternative reproductive and life history strategies. A good example is the difference between different mating strategies in the Atlantic salmon (*Salmo salar*). Dominant males grow rapidly, migrate to sea, delay maturation, and mate guard females whose eggs they can easily fertilize.

Sneaker males do not migrate to sea, have limited growth, have early maturation, cannot mate guard females, and have to avoid mate-guarding males to try and fertilize females' eggs. However, they can outcompete dominant males in sperm competition for fertilization by producing higher-quality sperm (Vladić and Petersson 2015).

## Conclusion

Life history theories state that organisms maximize their Darwinian fitness through optimization of their life history traits as a function of multiple trade-offs. The study of life history trade-offs and of the diversity of life histories helps to understand the main selection pressures that organisms are facing in addition to why and how they are adapted to their environment. To gain insights on the diversity of life histories, it is important to not only understand the ultimate consequences of trade-offs but to also understand the proximate mechanisms underlying them. Finally, life history traits are not limited to morphological and reproductive traits but include physiological and behavioral traits. The pace-of-life syndrome hypothesis specifies that a suite of metabolic, hormonal, immunity, and behavioral traits have coevolved with life history particularities related to different ecological conditions (Réale et al. 2010). This hypothesis therefore provides an integrative framework to study both proximate mechanisms of behaviors and their ultimate consequences for life history evolution.

## Definition

Lifetime expectancy can be defined as either the average or the maximal duration of the lifetime (lifespan) of individuals of an animal species after birth or eclosion. The average or typical (modal) duration of individual lifespan is dependent on a variety of factors, including habitat, habits, extrinsic mortality rates, and environmental variables, but still varies within the maximal known lifespan of the species.

## Introduction

How long an animal lives is not a freely variable amount of time that depends simply on extrinsic, environmental factors. Fruit flies and lab worms live not much more than 3 weeks in the best of conditions; mice hardly ever reach 2 years of life even if kept fed, sheltered, and safe from all predators in controlled animal housing facilities; the healthiest humans are still not expected to live much more than one century. The fact that different animal species have characteristic maximal lifetime expectancies, and that these vary across species from under 1 day to over one century, strongly indicates that there are innate, biological determinants of longevity. This entry explores some of the current knowledge and theories about what factors determine lifespan, and therefore lifetime expectancy.

## Life History, Biological Time, and the Pace of Life

How much of life goes by for different species within a similar period of time? Only 4 days separate the day when an individual *Caenorhabditis elegans* worm ecdyses and when it is biologically capable of laying eggs and reproducing, and only under very rare circumstances and conditions will that worm individual still be alive 1 month later. In contrast, humans are still just about as helpless at 1 month as they were at 4 days of age, and it will take over a decade until they become biologically competent to reproduce. Although the biological bases of animal life are universal, life runs at a different *pace* for different species: *biological time* is not directly comparable across animals. The combined, absolute, and relative duration of time spent in each stage of life – embryonic development, infancy/postnatal growth, adolescence, sexually competent adult life, old age – is referred to as the *life history* of a species. How come biological time and therefore life history varies by four orders of magnitude across species remains one of the main fundamental unanswered questions in biology – although important insights have occurred recently.

The temperature at which the body functions and therefore at which all chemical reactions occur is of course a major variable across the enormous diversity of non-vertebrate animals, and also among fishes, amphibians, and non-avian reptiles. Broadly speaking, the warmer the temperature at which the body of an animal works, the faster its metabolic rate (as expected from simple thermodynamics), the faster the pace of life, and the shorter the lifespan of the animal. Similarly, metabolic rate per gram of body also decreases as animals become larger, and along with it the pace of life seems to slow down, and life expectancy increases. However, this relationship breaks down upon closer inspection. For instance, birds function at systematically higher body temperatures and have predictably higher metabolic rates than mammals of similar size, yet birds have a lifetime expectancy that is as much as 20 times that of rodents. Indeed, as explored further below, even when body temperature is removed from the equation by nature, life

history remains enormously variable. Across endotherm, homeotherm animal species (birds and mammals), songbirds live systematically longer lives than primates, which in turn live systematically longer lives than non-primate mammals of similar body mass.

Despite the apparent regularities across the entire animal phylum as a whole, it is obvious already at the most superficial level of observation that different animal species live at different rates. There is enormous diversity in life, and not one single way or pace of living. What determines biological time for different animal species?

## Extrinsic Factors

For decades, one favored explanation for the different life histories spanning four orders of magnitude across animal species, from one day to one century, was extrinsic mortality rates: the higher the likelihood of being predated upon on an average day, the stronger is the selective pressure for a species to develop quickly and reach sexual maturity earlier rather than later, which over generations would lead to lifetime acceleration as an adaptive feature driven by natural selection (Charnov 1993). As a consequence, longevity should increase as the probability of death caused by extrinsic factors decreases (Austad and Fischer 1991). In support of that proposition, there are known instances in which documented changes in predation risk have indeed been accompanied by changes in lifetime expectancy in the predicted direction within particular species. In the case of birds, flight has been evoked as a factor that significantly lowers predation risk and thus might account for the slower life history and longer life expectancy (Munshi-South and Wilkinson 2010) – although in that case *all* bats would be expected to be longer-lived than other mammals of similar size, which is not the case. Besides the scant experimental support, one major difficulty with this line of reasoning is that it presupposes that biological life histories are highly plastic, which is not compatible with available evidence. Most importantly, pinning the determination of lifetime expectancy down on extrinsic factors runs inevitably into a mathematical tautology (since increased longevity *is defined* as lower

probability of death at any age) and circular reasoning that do not account for *how* diversity in biological lifetimes would arise in the first place, before any selection occurs. Another strong argument against extrinsically determined life histories is that there are striking regularities in lifetime expectancy across species, explored below, that make it far more likely that there are intrinsically, biologically determined mechanisms that set the pace of growth, maturation, and aging.

### **Intrinsic Factors: Rate-of-Living and Rate-of-Aging**

One highly influential theory for an endogenous mechanism of setting the pace of life is the appropriately named Rate-Of-Living theory (Pearl 1928), according to which the duration of life of an organism is curtailed upon the exhaustion of a fixed quantity of something vital at a rate proportional to the metabolic rate. The value of this fixed quantity would depend on an intrinsically, genetically determined “metabolic potential,” and also on the rate of metabolism, which may be determined extrinsically (by environmental temperature, e.g., in the case of heterotherm animals) or intrinsically (in the case of endotherm animals).

As mentioned above, body temperature does affect all chemical reactions in an organism, including proteostasis (the balance between rates of protein synthesis, folding, damage, and disposal), and impact life history in *C. elegans* as expected, shrinking life history and shortening lifetime expectancy as populations are raised in warmer environments (Stroustrup et al. 2016). Shorter life histories as a whole, and lifetime expectancies, in particular, are predicted by models that presume progressive accumulation of damages to both proteins (Santra et al. 2019) and DNA (Hoeijmakers 2009), depending both on temperature and metabolic rate (West 2018). The process of accumulation of damages to proteins, DNA, lipids, and other vital molecules and structures is now widely considered as an underlying feature of aging. Thus, variation in lifetime expectancy across animal species and individuals is currently largely presumed to originate from variations in the rate of aging. At this point, however, variations in the rate of aging across species

remain mostly an intuition not yet backed by strong experimental support. For example, while the rate of telomere shortening and presumably DNA repair ability is an excellent predictor of maximum longevity across a small sample of nine warm-blooded species (Whittemore et al. 2019), it is possible that it is the larger accumulation of DNA damages with a longer life that makes DNA repair ability appear higher in longer-lived species. It is difficult to tease apart cause and consequence in the generation of lifetime diversity from simple correlations.

### **Resilience to Aging**

Recently, however, a novel variable brought into play did make simple correlations highly revealing by showing that body size and metabolic rate are not required to explain the wide range of variation in lifetime expectancy across warm-blooded animals, or the clade-specific differences (Herculano-Houzel 2019). The combination of a large dataset on life history with a novel dataset on the numbers of neurons that compose the brains of different species showed that across birds and mammals alike (not including bats, which were not available for analysis), variations in the estimated number of neurons in the pallium (cerebral cortex) account for as much as 74% of the variation in lifetime expectancy (measured as maximal longevity) across a sample of 750 species. Most importantly, clade-specific differences across birds, primates, and other mammals disappear; and after accounting for the number of pallial neurons in each species, residual analysis shows that body size and specific metabolic rate are mathematically irrelevant. Thus, the more the cortical neurons found in the adult brain of a warm-blooded species, the longer its life history, with sexual maturity reached only at older ages and expanded maximal longevity after reaching maturity – and humans are no exception (Herculano-Houzel 2019). It is too early to tell what lies underneath that correlation, and even if numbers of cortical neurons do have a determining role in life history and longevity or are simply a proxy for the true determinant factor, although it has been proposed that the correlation *is* causal through increased resilience to aging incurred with more

postmitotic, cortical neurons in the brain (Herculano-Houzel 2019). Importantly, this proposition is well in agreement with the large body of evidence showing that in a wide range of animal species, and also across individuals, caloric restriction and exercise, the two manipulations that undisputedly extend longevity, also protect neurons in the cerebral cortex in a variety of ways.

## Conclusion

Biological time differs across species, as evidenced by the fact that there is enormous diversity in lifetime expectancies across animal species, and that this diversity in turn originates from similarly enormous diversity in life histories. The pace of life does have some dependence on factors that affect metabolic rate, like body size and temperature, especially across heterotherm animals. However, a new possibility to be investigated is that in homeotherms, the damages that define aging accumulate at similar rates, regardless of metabolic rate, and a new factor comes into play: the number of cortical neurons in the network that maintains the physiological integration of the body, in such a way that the larger that population of neurons is, the more resilient is the network, and so longer the body remains viable.

## Light/Dark Cycle

Danilo Eugênio de França Laurindo Flôres  
Universidade de São Paulo, São Paulo, SP, Brazil

## Definition

Light/dark cycle refers to the periodic alternation between different levels of illumination in an environment.

## Concept, Implications and Applications

Light/dark cycles are oscillations in the light level in a given natural or artificial environment, with a regular periodicity. The natural light/dark cycle of our planet has a period of 24 h. Most natural and artificial light/dark cycles have a state of complete darkness (dark phase), alternated with a state of

bright light (light phase). However, the dark phase may consist of dim light, in some ecological contexts or in artificial light/dark cycles built for specific purposes, as explained below.

The natural daily light/dark cycle experienced at a point on Earth results from the rotation of the planet around itself, which promotes the periodic oscillation between bright days and dark nights every 24 h, due to alternate exposure to the Sun. No natural light is expected to reach environments at depths below 10 cm in land or 1000 m in the oceans; thus, these places are devoid of light/dark cycles (Beale et al. 2016). What we recognize as light is only a portion of the compound electromagnetic radiation that comes from the Sun during the light phase (Spitschan et al. 2016). The total Sun radiation is composed of different wavelengths, and “light” consists of the wavelengths that stimulate the human eye (400–700 nm). In the dark phase, extra illumination may come from the Moon, depending on the lunar phase. A clear sky on a cloudless day may be as bright as 100,000 lux, while the illuminance of a full moon night sky is less than 1 lux (Spitschan et al. 2016).

In natural environments, there are smooth transitions between the light and the dark phases, the twilights (Roenneberg and Foster 1997). Twilights are formally defined as the times of the day when the Sun is below the horizon, at angles between 0° and –18° (Daan and Aschoff 1975; Spitschan et al. 2016). Besides the change in light level, a daily variation in light color is also found within the light phase, mostly during the twilights. This implies that, at different times of the day, there is a change in the relative proportions of the wavelengths that reach the Earth’s surface (Spitschan et al. 2016). Such changes result from the different angles with which the Sun radiation passes through the atmosphere.

Due to the Earth’s round shape and its inclined axis of rotation at 23°, the proportion between light and dark hours (photoperiod) is not the same throughout the year and along the latitudes (Bradshaw and Holzapfel 2007). At low latitudes close to the equator, the yearly variation in photoperiod is smaller. At extreme latitudes close to the poles, profound photoperiod variations occur, with constant nights in the winter and constant

days during summer, although there are still daily oscillations in light composition (Krüll 1985).

Along with the light/dark cycle, daily changes in abiotic and biotic variables constitute the day/night cycle experienced by organisms within the 24 h, in diverse natural environments. Different from most of the other variables, the light/dark cycle is precisely stable from year to year at the same location, so that today’s light/dark cycle will be repeated precisely, on the same day in the next year or 10,000 years from now (Bradshaw and Holzapfel 2007). However, changes in weather, vegetation cover, and terrain may impact the daily light oscillation perceived in specific microenvironments (DeCoursey 1989).

The predictability of the natural light/dark cycle rendered it as a pervasive environmental cue that is used as a time reference for living organisms to adjust themselves to the day/night cycle. The existence of daily changes in light, since ancient geological times, was an evolutionary pressure that promoted the selection and consolidation of endogenous daily variations in physiology of most organisms, the circadian rhythms. These rhythms are the expression of circadian clocks, self-sustained physiological pacemakers that are synchronized daily by the light/dark cycle (Roenneberg and Foster 1997). Thus, the role of the light/dark cycle is not only an acute signal of day and night but also a dynamic signal that sets the phase and period of endogenous circadian clocks. Since photoperiod also changes in a precise fashion along the year, it is a trustworthy cue to the seasons. Therefore, similarly to its role in the daily timing of circadian rhythms, the light information is also used as a cue to the time of year (Bradshaw and Holzapfel 2007). Photoperiod adjusts the timing of annual rhythms in reproduction, migration, and other biological phenomena in many species.

Given its importance in signaling time to living organisms, artificial light/dark cycles have been widely used in experimental research on circadian rhythms and photoperiodic responses. Most experimental protocols apply rectangular light/dark cycles, built from abrupt transitions between the light and dark phases (DeCoursey 1989),

although some studies attempt to model natural twilights and the changes in light color. Depending on the purpose of the study, experimental research may use light/dark cycles with different periods, different proportions between the light and dark hours, and with variable average and amplitude in light level oscillation.

The behavior and habitat use of an animal, in the temporal and spatial dimensions, contribute to how it experiences the daily light/dark cycle (DeCoursey 1989; Roenneberg and Foster 1997). For instance, migrating organisms that travel through varying latitudes and longitudes experience unique light/dark information. Dendwelling, fossorial, and subterranean animals only expose to light while outside of their burrows in the light phase. Likewise, human beings in urban locations stay within low-light environments during most of the day and only experience full natural light while in transit between home and work.

Human societies have yet another source of variation in the light/dark cycles. Urban cities are illuminated pervasively by electrical light, which imposes exposure to light at times when the natural environment should be in the dark (Spitschan et al. 2016). Light exposure at night is even greater for individuals that work night shifts. This light information at unexpected hours has been associated to disturbances in human sleep and circadian rhythms and has been correlated to health issues, such as obesity and cancer (Navara and Nelson 2007). Experimental light/dark cycles that mimic artificial light at night have also found concerning effects on the health of model laboratory organisms (Navara and Nelson 2007). Moreover, the disruption of natural light/dark cycles by light at night has impacts on the physiology and ecology of nonhuman organisms within and close to urban centers (Irwin 2018).

## Linkage Analysis

Kishore Sesham and Hare Krishna  
Department of Anatomy, All India Institute of  
Medical Sciences (AIIMS), Jodhpur, Rajasthan,  
India

### Introduction

Linkage analysis is a well-established statistical method in the field of reverse genetics, where in the predisposing gene(s) causing a heritable trait is/are identified.

### Description

#### Basic Concepts

Linkage analysis being a statistical method requires understanding of some basic terms such as recombination fraction, likelihood functions, maximum likelihood estimation, and odds ratios.

#### Genetic Recombination, Linked Genes, Genetic Distance, and Physical Distance

Genetic recombination is a biological phenomenon occurring in the parental gametes during the process of meiosis before eggs and sperms are formed. This phenomenon leads to exchange of chromosome material between homologous chromosomes via a crossover event with the crossover location thought to be determined by chance. Thus, each child inherits a unique set of recombinant chromosomes of their grandparents.

Genes located close enough to each other on a chromosome and whose expected crossover rate within the genetic material separating them at meiosis is less than 50% are said to be linked genes.

The distance between two or more linked loci can be expressed in two ways, i.e., by genetic distance or physical distance. Physical distance is the number of nucleotide base pairs present between them and is determined by DNA sequence analysis, whereas genetic distance is the frequency of recombination between two loci and is determined by observing recombination in a set of families. Thus, genetic distance is relative and is dependent on the distribution of crossing-over with recombination along each chromosome. Genetic distance may not reflect the physical distance because crossing-over is not evenly distributed along all chromosomes resulting in blocks of nonrecombinant stretches of DNA existence in between (Nussbaum et al. 2007).

#### Recombination Frequency as a Consequence of Genetic Distance Between Two Loci

Linkage occurs when two gene loci are physically close enough on the same homologous chromosome that they tend to be transmitted together. Estimating the genetic distance between any two gene loci relates to how often the genetic recombination does or does not occur between those loci. The recombination fraction, often represented as  $\theta$ , is calculated by counting the number of recombinant offspring for a given pair of loci divided by the total number of offspring (recombinants plus nonrecombinants). It measures the proportion of recombinations observed between two loci in a group of offspring. If  $\theta=0$ , it means the two loci are very much close to each other and have very high chance of getting inherited together. If  $\theta=0.5$ , it means that the two loci are far apart and assort independently. All the values of linkage lie between 0 and 0.5 indicating the varied degrees of linkage. A recombination rate of 1 (100%) is considered to be a Morgan (M) unit. A recombination frequency of 0.01 (1%) corresponds to one centiMorgan (cM). The centiMorgan is used as a typical unit of genetic linkage. This unit is defined on the basis of relative chance of separation of

different traits per meiotic division. A distance of 1 cM between the two markers that are coding for different traits is separated to different chromosomes on average once per 100 meiotic product, thus once per 50 meioses (Griffith et al. 2000).

#### Determination of the Relative Distance of Three Gene Loci Using Recombinant Frequency

The genetic distances and the order of three loci can be determined by a testcross of parental genotypes. For example, there are three gene loci A, B, and C of unknown distance from each other, and their observed recombination frequencies using test cross of parental genotypes are as follows: The distance from locus A to locus C is 0.06 (6%); the distance between locus B and locus C is 0.29 (29%); and the distance between A and B is 0.31 (31%). Thus, the three genes are located in the order A–C–B (Vogel et al. 1997).

#### LOD Scores Method Analysis

This method was designed by Newton Morton in 1955. LOD score represents the logarithm in base 10 of the odds of linkage of a trait at a recombination fraction  $r$  with a particular marker locus compared to a recombination fraction ( $\theta$ ) of 0.5 between the marker and the trait. It provides a different way of assessing the significance of a linkage signal, other than a  $p$ -value. This method is an efficient and economical method for studying families because once a decision is reached, it is not necessary to study additional families.

$$LOD = Z$$

$$= \log_{10} \frac{\text{probability of birth sequence with a given linkage value}}{\text{probability of birth sequence with no linkage}}$$

$$= \log_{10} \frac{(1 - \theta)^{NR} \times \theta^R}{0.5^{(NR+R)}}$$

LOD score greater than 3.0 is an evidence for linkage, whereas score less than -2.0 is considered evidence to exclude linkage (Morton et al. 1955).

#### Linkage Analysis Testing Procedures and Software Programs

Linkage analysis utilizes data on family structures, trait values, and genome-wide markers and involves tagging segments of a person's genome with markers that allow identification of segments

that have been inherited through the family along with disease and detects the degree of recombination between those genetic markers and traits in that particular family pedigrees. The genetic markers used in this method are typically **microsatellites** or SNPs that are genotyped and tested in a study sample of pedigrees, and those showing the strongest statistical evidence of linkage exceeding a predetermined threshold localize the trait gene to the chromosome segment where the markers reside. Parametric linkage (model based) analysis is used for Mendelian traits that follow a specific pattern of inheritance consistent with a single gene, i.e., X-linked, autosomal recessive, or autosomal dominant. For genetically complex traits (due to incomplete penetrance and/or genetic heterogeneity), nonparametric linkage analysis is used where the initial approach is similar to the one used for Mendelian traits, but the mode of inheritance is not known and not specified. Various computer programs have been included to make linkage analyses more precise and powerful which are briefly listed in the following table.

The following are the web pages for various linkage analysis software listed above:

9. SOLAR. [http://www.sfbr.org/Departments/genetics\\_detail.aspx?p=37](http://www.sfbr.org/Departments/genetics_detail.aspx?p=37)

#### Applications

Linkage analysis studies have been used in routine OPDs to do positional cloning of genes in disorders such as cystic fibrosis (autosomal recessive),

**Linkage Analysis, Table 1** showing the list of various softwares for linkage analysis that can be used for binary traits and quantitative traits in large pedigree families and nuclear families (Cantor et al. 2013)

*Par* = Parametric model; *NP* = Nonparametric model; *Both* = parametric and/or nonparametric

neurofibromatosis type-1 (autosomal dominant) using parametric models as well as for complex disease gene position cloning such as Crohn's disease using nonparametric models. See Table 1 for software for analyses.

### Advantages and Drawbacks

Linkage methods are particularly useful for the detection of rare variants with a large effect size in the population. These methods, however, have shown inconsistent results for common diseases. Factors such as heterogeneity, pleiotropy, reduced penetrance, and variable expressivity, in addition to variability in environmental exposures, weaken the power of linkage studies in complex traits. Although, linkage methods are able to identify candidate regions, the identified regions are much larger, sometimes spanning up to 40 Mb. Due to the availability of "next-generation" DNA sequencing and its promise to allow identification of the rare variants, interest in linkage analysis methods is undergoing a renaissance.

### Conclusion

Since the time it is developed, several methods and computer programs have been included to

make linkage analyses more precise and powerful. Linkage studies were used in the past only to isolate genes that cause rare genetic syndromes. Coupled with whole genome sequencing, this method has been successfully used to identify the association of rare variants to phenotypic traits such as hearing impairment, familial goiters, and familial hypertension. Thus, linkage analysis is again emerging as an extremely useful method in genomic analysis.

## Synonyms

Fats; Membrane lipid

## Definition

Lipids are large nonpolar water-insoluble biomolecules that provide ample amount of energy in less volume and stored inside the body in different form to perform different physiological functions.

## Introduction

Biological lipids are chemically diverse group of organic compounds which are insoluble or only poorly or partially soluble in water. They are readily soluble in nonpolar solvents such as either chloroform or benzene. The water or

polar insolubility of lipids is due to the hydrophobicity of the predominant hydrocarbon chains (-CH<sub>2</sub>-CH<sub>2</sub>-CH<sub>2</sub>-) in their structures. Lipids are not polymers like the other biological molecules like proteins, nucleic acids, and polysaccharides. Lipid molecules are considered as the most crucial building block of cell membrane and cell signalling mediators. It is also an energy-providing molecule and stored as fat in the body. Although it is potentially beneficial, deregulation of lipid can become toxic and pathogenic for the cell causing cell death. The surplus-stored lipids are mobilized during starvation to provide energy or available for phospholipid synthesis. The lipids in the droplet form are also protective against lipotoxicity and oxidative stress.

## Classification of Lipids

Lipid can be classified based on its structural modification such as:

- (a) Fatty acid
- (b) Triacylglycerols (lipid droplet)
- (c) Glycerophospholipids/phosphoglycerides
- (d) Sphingolipids
- (e) Steroids
- (f) Others such as waxes, terpenes, eicosanoids

## Fatty Acids

Fatty acid is one of the simplest forms of lipids that helps to build the complex form. They are long-chain hydrocarbons (4 to 36 carbons long) with one carboxyl group. In biological system, usually it contains an even number of carbon atoms. The 16 and 18 carbon fatty acids are most common. The acyl chain may be saturated or unsaturated. Unsaturated fatty acids may contain one or more double bonds. Being amphipathic by nature they have both nonpolar and polar ends. From the numbering of carbon, the first carbon attached with the carboxyl group (-COOH) is considered as  $\alpha$  carbon followed by  $\beta$ ,  $\gamma$ ,  $\delta$ ,  $\theta$ , etc., and the last carbon is the omega  $\omega$ .

## Saturated Fatty Acid

See Table 1.

## Unsaturated Fatty Acid

The predominant fatty acid residues are those of  $C_{16}$  and  $C_{18}$  species palmitic, oleic, linoleic, and stearic acids in higher plants and animals where over half of them are unsaturated and are often polyunsaturated. Fatty acids with  $<14$  or  $>20$  carbon atoms are unlikely to be in nature. Most fatty acids have an even number of carbon atoms concatenation of  $C_2$  unit. Bacterial fatty acids are commonly branched and hydroxylated or contain cyclopropane ring but rarely polyunsaturated.

## Essential Fatty Acids

Due to the paucity of enzyme to introduce double bonds in carbon atoms beyond  $C-9$  in the fatty acid chain, mammals cannot synthesize linoleate and linolenate. The two essential fatty acids are linoleate and linolenate. The term essential means that they must be obtained from the diet because they are required by an organism and cannot be endogenously synthesized. Endogenously synthesized fatty acids are termed as nonessential.

## Melting Point of Fatty Acids

Chain length and degree of unsaturation are the two parameters which denotes the melting point of fatty acids. Melting point is proportional with the chain length and inversely proportional to the

unsaturation or number of double bonds. Unsaturated fatty acids are rigid due to the presence of double bonds. Consequently, unsaturated chains cannot pack themselves in crystals efficiently and densely as saturated chain, so they have lower melting point as compared to saturated fatty acids. Similarly the unsaturated fatty acids with cis unsaturated fatty acids have lower melting points than the trans unsaturated fatty acids.

## Triacylglycerol (Lipid Droplets)

The fats and oils that occur in plants and animals consist largely of mixtures of triacylglycerol (triglycerides and neutral fats). These nonpolar, water-insoluble substances are fatty acid triesters of glycerol. It acts as energy reservoirs in animals and is therefore most abundant class of lipids even though they are not components of biological membrane. Lipid droplets are emerged from the ER and are phospholipid monolayer unlike bilayer membrane.

According to the identity and placement of their three fatty acid residues, they differ in structure. The so-called simple triacylglycerol contain one type of fatty acid residue. For example, tristearoylglycerol or tristearin contains three stearic acid residue. Mixed triacylglycerols contain two or three different types of fatty acid residues and named according to their placement on the glycerol moiety. Fats (solid at room temperature) and oils (liquid at room temperature) are complex mixtures of simple and mixed triacylglycerols whose fatty acid composition vary with the organism that produced them. In respect to storing metabolic energy, fats are a highly efficient because they are less oxidized than are carbohydrates or proteins and can yield more energy

**Lipid, Table 1** List of saturated fatty acid (Voet et al. 2008)

| Symbol | Common name    | Systematic name | Structure             | Carbon no. | No. of double bond |
|--------|----------------|-----------------|-----------------------|------------|--------------------|
| 12:0   | Lauric acid    | Dodecanoic      | $CH_3(CH_2)_{10}COOH$ | 12         | 0                  |
| 14:0   | Myristic acid  | Tetradecanoic   | $CH_3(CH_2)_{12}COOH$ | 14         | 0                  |
| 16:0   | Palmitic       | Hexadecanoic    | $CH_3(CH_2)_{14}COOH$ | 16         | 0                  |
| 18:0   | Stearic acid   | Octadecanoic    | $CH_3(CH_2)_{16}COOH$ | 18         | 0                  |
| 20:0   | Arachidic acid | Eicosanoic acid | $CH_3(CH_2)_{18}COOH$ | 20         | 0                  |

on oxidation. Furthermore, fats being nonpolar substance, it can be stored in anhydrous form requiring less energy as compared to glycogen in physiological condition.

Some of the key lipid molecules are chylomicron (formed in the intestine, carry dietary lipid to the circulation after a meal, and degraded in the liver), very-low-density lipid (VLDL, triglyceride-rich lipoprotein made in the liver and converted to lower density form), low-density lipid (LDL, cholesterol-rich lipoprotein produced from VLDL), and high-density lipid (HDL, produced in both the intestine and liver and carries cholesterol from the liver to periphery, considered as healthy lipid molecules in the body).

According to the lipid molecule shape, it forms different structure, such as cone-shaped monoacyl lipid forms micelle and diacyl lipid forms lipid bilayer (compact) or liposome (cavity inside).

## Phosphoglycerides

Phosphoglycerides or glycerophospholipids (GPL) are the major lipid components of biological membrane. Phospholipid is an amphipathic molecules constructed from four components: a platform of glycerol or sphingosine backbone to which the fatty acids are attached, the fatty acyl chain, a phosphate the head group, and head group substituent attached to the phosphate. GPL are amphiphilic molecules with nonpolar aliphatic

“tails” and polar phosphoryl-x “heads.” The fatty acids at the sn-1 position (C-1) tend to be saturated (no double bond) or monounsaturated (one double bond), whereas the sn-2 (C-2) fatty acids are mostly monounsaturated or polyunsaturated (multiple double bond) (Table 2). The c-3 hydroxyl group of the glycerol backbone is esterified to phosphoric acid (the head group) where the head group substituents are attached. The simplest phosphoglyceride is phosphatidic acids where no further head substituents present are found in small amount in most natural system. The common alcohol moieties of phosphoglycerides are serine, ethanolamine, choline, glycerol, and inositol. If the alcohol is choline, the phosphoglycerides molecule is called phosphatidylcholine (lecithin), and if serine, then it is called phosphatidylserine, etc. Some GPL have common names, e.g., phosphatidylcholine are known as lecithins, and diphosphatidylglycerol the double glycerol phospholipids are known as cardiolipins (first isolated from the heart muscle). Plasmogens are GPL in which the c1 substituent to the glycerol moiety is bonded to it via an  $\alpha$ ,  $\beta$  unsaturated ether linkage in the cis configuring rather than through an ester linkage. Ethanolamine, choline, and serine form the most common plasmogen head groups (Fig. 1 and Table 3).

**Sphingolipids:** Nonglycerol but sphingosine (long-chain c-18 amino alcohol)-derived phospholipids are called sphingophospholipids or sphingolipids. They are also varied depending on their composition.

**Lipid, Table 2** List of Unsaturated fatty acid (Voet et al. 2008)

| Symbol  | Common Name    | Systematic name                                                                     | Structure                                                                         | Carbon no. | No. of double bond |
|---------|----------------|-------------------------------------------------------------------------------------|-----------------------------------------------------------------------------------|------------|--------------------|
| 16:1n-7 | Palmitoleic    | Cis- $\Delta^9$ -hexadecenoic/9 hexadecenoic acid                                   | $\text{CH}_3(\text{CH}_2)_5\text{CH}=\text{CH}(\text{CH}_2)_7\text{COOH}$         | 16         | 1                  |
| 18:1n-9 | Oleic acid     | Cis- $\Delta^9$ -octadecenoic/9 octadecenoic acid                                   | $\text{CH}_3(\text{CH}_2)_7\text{CH}=\text{CH}(\text{CH}_2)_7\text{COOH}$         | 18         | 1                  |
| 18:2n-6 | Linoleic acid  | Cis- $\Delta^9, \Delta^{12}$ octadecadienoic/9,12 octadecadienoic acid              | $\text{CH}_3(\text{CH}_2)_4(\text{CH}=\text{CHCH}_2)_2(\text{CH}_2)_6\text{COOH}$ | 18         | 2                  |
| 18:3n-3 | Linolenic acid | Cis- $\Delta^9, \Delta^{12}, \Delta^{15}$ octadecatrienoic/9,12,15 octadecatrienoic | $\text{CH}_3(\text{CH}_2)(\text{CH}=\text{CHCH}_2)_3(\text{CH}_2)_6\text{COOH}$   | 18         | 3                  |

**Sphingomyelin:** A fatty acid is joined to a sphingosine via an amide linkage to form ceramide (sphingomyelin) as a common structure of all sphingophospholipids. J.L.W. Thudichum in 1884 first coined the term “sphingo-” which means the riddles of the sphinx. Herbert Carter and colleagues in 1947 introduced the term “sphingolipide.” Sphingolipids are extremely versatile molecules which contribute to gather knowledge in animal and plant tissue in their healthy and abnormal disease state. *Sphingomonas* and *Sphingobacterium* are the few bacterial genera containing sphingolipids.

**Glycosphingolipid (glycolipid):** Lipid-containing carbohydrate groups are called glycolipids where glycosphingolipid is the important one and also third important component of membrane. Carbohydrate chains are connected at –OH group of C-1 of ceramide.

**Cerebroside:** Ceramides with monosaccharide chain.

**Lipid, Fig. 1** Phosphoglyceride

**Globoside:** Ceramides with oligosaccharide chain.

**Ganglioside:** Globoside with complex oligosaccharide containing N-acetylneuraminic acid, sialic acid, etc. Ganglioside moiety (GM), GM1 (M) where 1 sialic acid attached, GD (D) 2, and so on. In vertebrates alone depending on the variation in the carbohydrate chain, there are 188 of the complex as ganglioside. One of the important lipid of the CNS is the sphingolipids (Fig. 2 and Table 4).

**Steroid:** Complex derivative of triterpenes with four fused rings (cyclopentanoperhydrophenanthrene) is the steroids nucleus. The only polar component is the C-3 OH. One of the best examples is cholesterol, an essential component in animal cell membranes, which acts as a precursor for the biosynthesis of all steroid hormones and bile salts. In the cells cholesterol is as a fatty acid ester. In plants and fungi, it is absent (ergosterol an exception in fungi). Stigmasterol, sitosterol, and campesterol are some of the examples of plant cholesterol.

**Lipid, Fig. 2** Sphingolipid general structure

**Lipid, Table 3** Phospholipids and its different head group substituents

| Phosphoglyceride         | Head group substituents (x) |
|--------------------------|-----------------------------|
| Phosphatidic acid        | None                        |
| Phosphatidylcholine      | Choline                     |
| Phosphatidylethanolamine | Ethanolamine                |
| Phosphatidylserine       | Serine                      |
| Phosphatidylinositol     | Inositol                    |
| Phosphatidylglycerol     | Glycerol                    |
| Cardiolipin              | Phosphatidylglycerol        |
| Phosphatidylglucose      | Glucose                     |

**Lipid, Table 4** Sphingolipid and its different head groups

| Sphingolipid              | Head group (x)      |
|---------------------------|---------------------|
| Ceramide                  | Hydroxyl            |
| Sphingomyelin             | Phosphocholine      |
| Ceramide                  | Phosphoethanolamine |
| Glucose ceramide          | Glucose             |
| Galactose ceramide        | Galactose           |
| Complex glycosphingolipid | Oligosaccharide     |
| Ceramide-1-phosphate      | Phosphate           |

## Eicosanoid

The potent biological signaling molecules originated from 20 carbons, polyunsaturated fatty acids, and eicosanoic acids, particularly arachidonic acid. Prostanoids and leukotrienes are two examples. It also acts as local hormones.

Prostaglandins derived from prostanoid (C8-C12 form the cyclopentene ring) were first identified in human serum. Apart from RBC, all mammalian cells produce prostaglandin. Prostaglandin is designated as PG followed by A-I, which represent the nature of substitute and then numerical number for individuals.

## Metabolism of Lipids

### Biosynthesis of Lipids

#### A. Fatty acid biosynthesis

Each step 2 carbon number increases and even number fatty acids are produced.

**B. Lipid droplet biosynthesis:** In ER and other organelle, lipid droplets are biosynthesized and modified in a multistep process (Fig. 3).

1. Triacylglycerol synthesis (Fig. 4): Neutral lipid triacylglycerol and sterol ester synthesis is the first step in lipid droplet biogenesis. This form a lens-like structure of lipid.
  - (a) Glycerol-3-phosphate acyltransferase/ Acyl-CoA, b) acylglycerolphosphate acyltransferase/ Acyl-CoA, c) phosphatidic acid phosphate, d) diacylglycerol acyl transferase
2. Emergence and nascent lipid droplet formation: Nascent lipid droplets are formed by recruiting seipin and other lipids to the lens. Difference in surface tension of the two faces (luminal and cytoplasmic) of ER membrane causes release of lipid droplet.
3. Budding and growth of lipid droplet: Budding and fusion of lipid droplet define the

**Lipid, Fig. 3** Biosynthesis of lipid droplets (Voet et al. 2008)

Glyceroldehyde-3-phosphate  $\rightarrow$  Lysophosphatidic acid (LPA)  $\rightarrow$  Phosphatidic acid (PA)  $\rightarrow$  Diacylglycerol (DAG)  $\rightarrow$  Triacylglycerol (TAG)

**Lipid, Fig. 4** Biosynthesis of Triacylglycerol (TAG) (Voet et al. 2008)

end of the process (Olzmann and Carvalho 2019).

### C. Sphingolipid synthesis: Figs. 5 and 6.

## Catabolism of Lipids

Lipids are digested by lipase enzyme into fatty acid and glycerol. For example, phospholipase A1 acts in the C1 ester linkage of fatty acyl with glycerol backbone, phospholipase C in the phosphoester bond attached with glycerol backbone at C3. The fatty acids undergo beta oxidation.

### A. Fatty Acid Beta Oxidation

It follows four steps.

- Activation of fatty acids: Acyl-CoA attached at the terminal end of fatty acid and form fatty acyl-CoA in an energy-dependent manner.
- Formation of ketone at the beta position: At the beta carbon it is oxidized to form ketone ( $-C=O$ ) from  $CH_2$  by three reactions.
- In the final step, thiolysis form the acetyl-CoA and 2C less fatty acyl chain with the help of  $\beta$ -ketothiolase and add another CoA to the remaining acyl chain.
- The cycle continues to form half the number of acyl-CoA ( $N/2$ ), if it is even

number of fatty acid, whereas 1 propionyl CoA and  $(N/2-1)$  number of acyl-CoA is formed. Here  $N$  = carbon number of fatty acyl chain. The NADH and FADH<sub>2</sub> produced as a reaction intermediate are utilized to form ATP via electron transport chain complex.

- Similarly alpha and omega oxidation happens in alpha and omega carbon of fatty acyl chain. Refsum disease is one example of lack of alpha oxidation. For unsaturated fatty acid, the unsaturation shift to form ketone at beta position of carbon and the same steps are followed as described in beta oxidation.

### B. Degradation of Sphingolipid

## Functions of Lipid

- Fat serves as a food reserve for both plants and animals. It also helpful to provide energy supply for the hibernating and aestivating animals.
- In migratory birds, fat deposition (Zugdisposition) is an indication and helpful for migration.
- They provide more energy 9.3 Kcal/gm than carbohydrate (4.5Kcal/gm) in less volume.
- Due to capability of conversion of fat to carbohydrate, fat can be stored in the oil seeds.

**Lipid, Fig. 5** Biosynthesis of Sphingolipids (Voet et al. 2008)

**Lipid, Fig. 6** Ceramide synthesis (Voet et al. 2008)

- (e) Presence of polyunsaturated form, it provides thermal insulation to many animals living into the cold temperature. Blubber, a thick fatty layer in whale, and polar bear are two examples.
- (f) It also helps in protecting from UV radiation and loss of water.
- (g) Brown fat in infant also helps in thermogenesis.
- (h) Acts as a shock-absorbing cushion for different vital organ like eye balls, gonads, kidneys, etc. in the human body.
- (i) Edible oils are used as cooking. Animal milk fats are also used for the production of butter, ghee, etc.
- (j) Soap is prepared from animal and plant lipid.
- (k) In paint industry dry oil is useful.
- (l) Wax helps to form a protective layer in animal fur to avoid evaporation.
- (m) Myelin sheath of the neurons is also made up of lipid.
- (n) Cell membranes are formed from phospholipid molecule.
- (o) Terpene which is a plant product is used as terpene oil, is a fatty substance.
- (p) Acts as a lubricant for many animals.
- (q) Fat as a source of metabolic water in extreme desert conditions.

## Diseases

### A. Relationship Between Lipid Composition and Disease

The different diseases related to lipid composition and alteration are categorized mainly due to genetic or by lipid itself or lipidomic changes. The tables here listed different form

of disease and its reasons, substance accumulation, and dysfunctions (Haryama and Riezman 2018) (Table 5).

### B. Dysregulation of Lipid Droplet-Related Disease

In the formation and degradation of lipid droplets, different disease pathologies are found in the human. The following tables listed the details (Olzman and Carvalho 2019) (Table 6).

### C. Dysfunction of Sphingolipid Metabolism-Associated Disorders

The following table characterized the different diseases related with deficiency in the enzymes involved in the sphingolipid metabolism causing impairment and toxic substance accumulation (The table is taken from the medical biochemistry page by Michael W king, <https://themedicalbiochemistrypage.org/sphingolipids.php>) (Table 7).

## Conclusions

In brief lipids are one of the most important biomolecules which provides more energy in less volume compare to other important biomolecules like carbohydrate. Simultaneously it has different physiological function and also helps in the construction of neuron forming myelin sheath. It acts as insulator, protector, and storage of foods in animals. Basically it is in the most common TAG form. The membrane lipids are phospholipid. It is present in the form of sphingolipid, cholesterol, prostaglandin, eicosanoid, wax, oil, etc. Lipids are degraded by different lipases and also undergo oxidation. Dysfunction of lipids or dysregulation of lipid metabolism in the body causes different diseases.

**Lipid, Table 5** Categorizing of disease related to lipid dysfunction

| Diseases                    | Reasons                                                   | Substance accumulation                 | Dysfunction               |
|-----------------------------|-----------------------------------------------------------|----------------------------------------|---------------------------|
| Genetic disease             | Mutation or single nucleotide polymorphism-related enzyme | Aberrant lipid composition             | Biological dysfunction    |
| Disease caused by lipids    | Upstream cause                                            | Aberrant lipid composition             | Biological dysfunction    |
| Noncausal lipidomic changes | Biological dysfunction<br>Changes in cellular composition | Secondary changes in enzyme expression | Aberrant lipid metabolism |

List Memory Effects (Primacy and Recency)

Anthony A. Wright  
Department of Neurobiology and Anatomy,  
McGovern Medical School, The University of  
Texas Health Science Center at Houston,  
Houston, TX, USA

List memory has been studied since the experimental study of behavior began (Ebbinghaus 1902). List-memory results are displayed as a serial position function, usually showing best memory for items at the beginning of the list (the primacy effect) and at the end of the list (the recency effect) – a U-shaped serial position function. These serial position effects and their changes over time (retention delay) have had a profound impact on concepts and theories of how human memory works (e.g., Crowder

1976). List-memory studies can be more informative about how memory works than single-item memory studies because in the real world events are almost never encountered in isolation and are imbedded in a surrounding stream of other events. In order to further extend the role of list memory in understanding memory generally, nonhuman animals need to be tested in these same list-memory tasks for direct species comparisons.

The major impediment to testing animals in list-memory tasks has been their inability to remember even single items for more than a few seconds. Accurate memory is essential to interpret changes that occur over time in the form of the serial position functions and what these changes might reveal about the underlying processes of memory. The conundrum about animal's fleeting memory is how they could have survived in the natural environment if they could not remember food locations, mates, alpha conspecifics, nesting sites, and predator locations for hours and days, let alone a few minutes.

As it turns out, the issue of fleeting animal memory was more due to the use of a small number of experimental stimuli than anything related to the duration of the animal's memory. The rationale for using a small number of testing stimuli was to use very simple stimuli and maintain high familiarity, which in turn was reinforced by commercially available testing apparatus that came with limited numbers of simple stimuli (e.g., colored geometrical shapes). In studies of memory (delayed matching to sample or delayed *same/different* tasks), the small number of testing items would have been seen dozens of times during any individual session and hundreds of times across sessions. When a test stimulus did not match the sample item on an individual trial, the animal could easily become confused because that test stimulus had been seen many times in previous trials. Research has since shown that with systematic increases in the number of testing stimuli memory accuracy dramatically increased, resulting in *same/different* abstract concept learning, accurate memory for lists of as many as 20 stimuli, and maintained accuracy over substantial delays between the list presentation and the test presentation (see entry ► [“Interference”](#)).

An advantage of studying list memory as opposed to single-item memory is the ability to study changes in memory for different list positions as the retention interval is increased, similar to human memory studies where extending the delay prior to a test produced a dissipation of the human recency effect. Originally, dissipation of the recency effect was thought to be due to passive “decay” through a lack of rehearsal of those items. Moreover, the primacy effect was thought to be due to active rehearsal of the first list items as presentations of subsequent list items were being made (Atkinson and Shiffrin 1968; see also entry ► [“Memory”](#)). Primacy effects had been considered to be unique to humans because no non-human animal had shown primacy effects. Such logic made good sense at the time because non-human animals were thought incapable of cognitive abilities to actively rehearse (initial) list items and therefore were not expected to show list-memory primacy effects, only list-memory recency effects.

## Visual List Memory

Contrary to common wisdom at the time that nonhuman animals were incapable of accurate list memory and could not produce serial-position primacy effects, a rhesus monkey was trained with 211 unique picture items (scenes, objects, people, animals, etc.) and tested with lists of 10 and 20 pictures. Each item of the ten-item list was presented for 1 s, with a 0.8 s interstimulus interval (ISI) and a 1.0 s retention interval (Sands and Wright 1980a, b). If the test item (in the lower screen) matched any one of the list items shown in the upper screen, then a *same* response (right lever movement) was correct, Fig. 1a. If it matched no list item, then a *different* response (left lever movement) was correct (see entry ► [“Same/Different Learning”](#)). These changes from a simultaneous *same/different* task to 10-item and 20-item serial probe recognition (SPR) task caused only slight disruption of performance. Performance was 86% correct with these ten-item lists. Performance was even a respectable 81% correct with 20-item lists. Shown in Fig. 1b are

**List Memory Effects (Primacy and Recency), Fig. 1** (a) Schematic of a ten-item list-memory testing procedure. A monkey hand and arm is shown starting a trial by pressing downward on a lever. List pictures are then sequentially presented on an upper screen. Following a delay, a single test picture is presented on a lower screen. The subject moves the lever to the right, a correct response

this monkey's serial position functions (SPFs) with ten-item lists compared to a human in the same task. The monkey's 10-item SPF is compared to its 20-item SPFs in Fig. 1c.

These serial position functions show both primacy and recency effects and were the first evidence of both these characteristic signatures of human list memory. These signatures of serial list memory have been replicated many times since with a variety of species including: apes, rhesus monkeys, squirrel monkeys, capuchin monkeys, and pigeons (see Wright 2007 for a review). Thus, animals show at least some of the important characteristics of list memory as do humans. Nevertheless, there was plenty of skepticism

("same"), indicating that the test picture was in the list. (Left lever movements would indicate that the test picture was not in the list). (b) Serial position functions for a rhesus monkey tested with 10- and 20-item lists and showing primacy effects good memory for the last list items and recency effects for the last list items. (c) Comparison to a human tested with the same ten-item lists as the monkey in (b)

about whether the rhesus monkey in the Sands and Wright (1980a, b) studies (or any animal subject) was actively rehearsing the pictures and therefore whether rehearsal was the root cause of the primacy effect. Rehearsal is a process that is very difficult to test objectively with human participants, let alone nonhuman animals. Nevertheless, procedures such as lengthening the interstimulus interval that should have allowed more time for rehearsal of travel slide pictures did not enhance the monkeys' primacy effect, (Cook et al. 1989) nor did such manipulation for rehearsal of kaleidoscope pictures enhance the humans' primacy effect. But by teaching names (codes) for 40 kaleidoscope pictures to

**List Memory Effects (Primacy and Recency), Fig. 2** *Top*: an example of a four-item list-memory *same* trial with kaleidoscope pictures for testing humans. *Bottom*: an example of a four-item list-memory *different* trial

with travel-slide pictures for testing monkeys and pigeons. Pictures and the white rectangle were presented on a computer screen with a black background

humans, these same participants then showed ISI effects, and the magnitude of the ISI effect was related to their rehearsal strategy as shown by overt rehearsals and from posttesting interviews (Wright et al. 1990). Most important, however, was that rehearsal did not affect the magnitude of the primacy effect, but instead it improved memory performance for the middle items (the dip in the serial position function). Together these results and findings suggest that many of the same processes that produce serial position effects found in humans can be found in rhesus monkeys – a nonverbal, nonrehearsing animal.

To explore what was responsible for primacy and recency effects, different species were tested with short four-item memory lists to accommodate pigeons, which had difficulty with lists longer than four items (e.g., Santiago and Wright 1984; Wright 1989, 1998b, 1999a, 2007; Wright et al. 1984, 1985). Lists of four “travel slide”

pictures were used to test rhesus monkeys, capuchin monkeys, and pigeons (Fig. 2, bottom). Lists of four kaleidoscope pictures were used to test humans (Fig. 2, top) to avoid ceiling effects and level the “playing” field for comparisons to the (nonhuman) animals (Wright 1999a; Wright et al. 1985). Four pictures were each presented for 1.0 s with 1.0 s interstimulus intervals between list items, and one of six retention intervals that varied from 0 to 100 s depending on the species. Typically, retention intervals were fixed for blocks of 20 trials with two 20-trial blocks with different retention intervals tested daily; all randomized combinations the six retention intervals were tested.

The serial position functions for four different species are shown in Fig. 3. All species showed changes in their serial position functions with retention interval. At the shortest delay, the serial position function was upward-sloping, showing virtually pure recency performance. As retention

**List Memory Effects (Primacy and Recency), Fig. 3** Serial position functions showing primacy and recency effects that change as a function of retention delay for monkeys, pigeons, and humans. (The fourth item is the last list item.) Mean group error bars are

shown below each serial position function. Different-trial performance is shown to the right of each serial position function. Animals were tested with travel-slide pictures, and humans were tested with kaleidoscope patterns as per Fig. 2.

delay increased, a primacy effect appeared, giving the function its characteristic U-shape. At the longest delays, the recency effect dropped out, and the serial position function was downward-sloping, showing virtually pure primacy performance. These same qualitative pattern of changes occurred in the serial position functions of all

species, but there was a time course difference for species. The dissipation of the recency effect took place in about 30 s for rhesus and capuchin monkeys, 10 s for pigeons, and 100 s for humans. The primacy effect began to appear in only 1 or 2 s after the end of the list presentation and was somewhat more rapid for rhesus monkeys and

pigeons than it was for capuchin monkeys and humans. These different time courses for the different species are quantitative differences. The similar pattern of SPF changes for the different species is a qualitative similarity showing similar visual memory processes for these species.

These systematic changes in the serial position functions serve to constrain the possible explanations for these memory changes as a function of the retention delay. Consider the consistent result that memory for the first list item (primacy effect) improves with retention delay. The appearance of the primacy effect with increasing delay is counterintuitive to the hypothesis that memory decays with time and has impacted explanations of how memory changes over time.

### **What the Delay Changes Reveal About Memory**

The increase in primacy memory with retention delay is difficult for most memory theories to handle. As previously mentioned, memory according to most theories is supposed to decay with time – a so-called law of disuse – otherwise known as forgetting. Such forgetting is often portrayed as a passive decay process – as the dissipation of the recency effect was portrayed for humans. The waning of the recency effect, like all forgetting, is a hallmark of most memory theories. Indeed, the passive decay of the recency effect in human memory contributed to the rising popularity of the study of short-term memory and the so-called cognitive revolution. The time course of the recency effect was supposed to be a measure of the short-term memory buffer. But even this (theoretical) concept has not survived the test of time. Recency effects have been shown for greatly extended time scales such as recall of United States Presidents (Roediger and Crowder 1976), and rugby scores by pub patrons (Baddeley and Hitch 1977). Notwithstanding any lingering debate over whether dissipation of the recency effect is brought about by passive decay, the same cannot be said about the primacy effect. If memory decays with time, then how can primacy memory (primacy effect) increase with delay time? Such increases with delay point to inhibitory processes that change with delay.

### **Visual List-Memory Conclusions**

Nonhuman animals show the important characteristics of primacy and recency list-memory effects, as do humans. In addition, the four species tested in the four-item visual list-memory task showed similar dynamic changes in their primacy and recency effects as the retention delay was increased – a qualitative similarity across species with widely differing evolutionary histories and neural architectures. Quantitative differences across species were shown in differences in time courses of these serial-position-effect changes with retention delay. If only one retention delay had been tested, then the conclusions would likely have been different. A single delay would have sampled a different point along the continuum of serial-position-function changes for the different species and dissipation of the recency effect or appearance of the primacy effect would have been a chance finding.

These similarities and differences in memory were made apparent by using short memory lists and investigating list memory over a substantial range of the effective retention delay. If longer lists (e.g., >10 items) had been used, then the early serial-position-function changes (e.g., emergence of the primacy effect) would have been lost because other items would have been presented during the time that these serial position function changes were taking place. Other tests of human list memory with short lists and difficult-to-code memory items (like kaleidoscope patterns) have shown similar serial-position-function changes (e.g., snowflake patterns, Neath 1993a, b; Neath and Knodler 1994; and antique car drawings, Korsnes 1995; Korsnes and Gilinsky 1993).

### **Auditory List Memory of Rhesus Monkeys**

The changing shape of the visual serial position functions as a function of delay produced similar patterns of change for the different species. Does all memory work this same way? For example, would auditory memory show similar serial-position-function changes? One could possibly point to the modality effect in human memory

(prolonged recency memory) that might be expected to extend the recency effect. Like with visual list memory, auditory list memory with monkeys has encountered severe impediments, including a string of failed attempts by several laboratories to train rhesus monkeys on even single-item auditory memory tasks. A breakthrough came when monkeys were required to touch and contact the source of the sound – the speaker. In that task, three speakers were positioned on different walls of an experimental chamber (Fig. 4).

Two rhesus monkeys were trained to touch copper screens in front of the speakers mounted in wooden cabinets (Fig. 4). By touching the center speaker, a sample sound was played (2 s),

followed by a second sound played from the two opposing speakers on the two sides of the experimental enclosure. They then selected one of the two side speakers to touch. If the test sound matched the sample, then the correct response was a touch to the right-side speaker (*same* response). Otherwise, the correct response was a touch to the left-side speaker (*different* response). Correct responses were reinforced with 3.5 cc of Tang orange drink. Sounds were selected from a 520-item set of natural/environmental sounds (e.g., steamboat whistle, wood chopping, pig grunts, bongo drums, water gurgling, reveille, insect buzzing, cash-register bell, toy train whistle, girls giggling, coins dropping, ducks quacking, xylophone, yodeling, geese, lion roar,

**List Memory Effects (Primacy and Recency), Fig. 4** Schematic of an auditory list-memory procedure for testing rhesus monkeys. *Top left:* Lists of auditory items (different sound effects) were presented from the front speaker. *Top right:* Following the list presentation and a delay, a single test sound was played (simultaneously)

from both side speakers. A right speaker touch was a *same* response, indicating that the test sound matched one of the list sounds. A left speaker touch would indicate that the test sound was did not match any list sound. *Bottom:* Mean auditory serial position functions for two monkeys with lists of 6, 8, or 10 sounds

electric drill, children's piano, motorcycle, squeaky door, sneezing, crumpling paper, frogs, Big Ben chimes, glass breaking, horse whinny; see Wright 1998a, b; Wright and Rivera 1997, for additional sounds). The serial position functions shown in the lower portion of Fig. 4 for lists of 6, 8, and 10 sounds show primacy and recency effects, similar in this respect to those for visual memory in Fig. 1. Visual SPFs, however, tend to emphasize recency effects, whereas auditory SPFs tend to emphasize primacy effects more than recency effects.

The monkeys' auditory memory emphasizing primacy effects is shown even more dramatically with delay manipulations following four-item auditory memory lists. Delays of 0, 1, 2, 10, 20, and 30 s tested in 32-trial blocks like in the visual-memory tests (Fig. 5, top).

The rhesus monkey's auditory four-item serial position functions revealed primacy and recency effects that changed with delay of the test item as they did in the rhesus monkeys visual list-memory tests, but surprisingly the auditory serial position effects were opposite and changed in opposite ways compared to the rhesus monkey's visual serial position functions, as shown in Fig. 5. Immediately following presentation of the sound list, the auditory serial position function showed a strong primacy effect and only a primacy effect. As the retention interval was increased to around

10 s, the auditory serial position function gradually took on the typical U-shaped form with primacy and recency effects. At 20- and 30-s retention delays, the auditory serial position functions showed only recency effects; performance was worst on the first item and rapidly rose to very good performance on tests of the last list item. There was as much as a 40% change in accuracy. These auditory serial position functions and their changes with retention delay were replicated in more than 13 independent experiments including: testing familiar versus unfamiliar items, eliminating center-speaker touches, varying the intertrial interval (time between trials) across four experiments (1.0 s, 0.5 s, 1.0 s, and variable 12.0–27.0 s), trial-by-trial intermixing of the six retention delays and retesting after 4 years of layoff from the task (Wright 1998a, b, 1999b, 2002; Wright and Roediger 2003).

The change from a primacy-dominated function to a recency-dominated function for monkey auditory memory was rapid, and the ability to recognize the fourth (last) item in the list dramatically increased in just a few seconds. Such recovery of recency information strongly implicates the presence of inhibition coupled with spontaneous recovery or some sort of release from inhibition over time. If such inhibitory processes were instrumental in these serial-position function changes, then proactive inhibition of memory

**List Memory Effects (Primacy and Recency), Fig. 5** Comparison of auditory and visual four-item serial position functions for rhesus monkeys tested at the same

six retention delays. The auditory and visual serial position functions are opposite in form and are shown to change in opposite ways with changes in delay

(e.g., memory retrieval) of the last list items would be strong initially, but such proactive inhibition would need to dissipate as the delay increased in order for memory retrieval of the last items to recover (see also entry “Retrieval”). Furthermore, when retrieval of memories of the last list items were recovered, then those retrieved memories might in turn retroactively inhibit memory retrieval of the first list items as the delay was extended further.

### Inhibition Effects in Auditory List Memory

One inhibition experiment most clearly draws comparisons between single-item memory and four-item memory by eliminating either the first three list items or the last three list items and with tests across all six of the delays (Wright and Roediger 2003). The logic of comparing list-memory performance to single-item performance might be best understood by considering the following: If proactive inhibition from the first items of the list dissipates with retention interval, then fourth-item performance from four-item lists should rise with longer retention intervals and eventually equal single-item performance. And the same logic should hold for retroactive

inhibition from the last three list items on first item performance at short retention intervals.

The list-memory functions for four-item lists shown in Fig. 6 are similar and they replicated those shown in Fig. 5. The left-hand panel shows fourth-item performance compared to mean single-item performance. Single-item performance is much more accurate than fourth-item performance over the shortest (0 s, 1 s, 2 s) retention delays. This large performance difference further demonstrates the considerable effect of proactive interference from the first three items on the monkey’s memory of the fourth item of the auditory list at these short delays. This is compelling evidence because otherwise fourth-item performance would be just like single-item performance at these short delays. Fourth-item performance did rise as delay increased and became equivalent to single-item performance at the longest retention intervals, demonstrating that proactive interference from the first three items largely dissipated as retention delay increased. Thus, proactive interference at short delays appears to be the primary factor contributing to the shape of the short-delay auditory serial position functions.

**List Memory Effects (Primacy and Recency), Fig. 6** *Left:* Single-item auditory memory compared to fourth (last) item of a four-item auditory memory list showing a performance “gap” (circled) in accuracy produced by proactive interference from the previous three list items on memory of the fourth (last) list item at shorter

delays. *Right:* Single-item auditory memory compared to the first item of a four-item auditory memory list showing a performance “gap” (circled) in accuracy produced by retroactive interference of retrieval memory of the first list item from the subsequent three list items at longer delays

There was also evidence that retroactive interference contributed to the shape of these serial position functions at the long retention intervals by showing that retroactive interference adversely affects the monkey's memory for the first list items. The right-hand panel of Fig. 6 shows performance for the first item of the list compared to the mean single-item performance across delays. In this case, single-item performance is much more accurate than first-item performance over the longest (20 and 30 s) retention intervals. This large performance difference at the longer delays demonstrates the considerable effect of retroactive inhibition at these delays. Retroactive inhibition must have occurred, otherwise performance would have been just like it was with the single item across all delays. The equivalent performance for the first list item and the single item at the shortest retention intervals demonstrates that retroactive interference from the last three items is largely absent at these short retention delays. As the retention delay increases, retroactive interference builds and eventually eliminates the primacy effects of the serial position functions. Thus, retroactive interference at long delays is the second process to explain the shape of these serial position functions and is the major factor contributing to the shape of the long-delay auditory serial position functions.

Other tests of inhibition among list items (but results not shown) include: (i) Separating list items (increasing the interstimulus interval from 1 to 2.5 s) to decrease interaction and inhibition among item memory which reduced 0-s delay primacy effects from 98% to 63% and was accompanied by an increase in recency effects from 40% to 79%; (ii) Adding just 2 s to the middle interstimulus interval (between the second and third list item) produced similar results; (iii) Substituting frequently repeated sounds for either the first two list items or the last two list items and testing with delays of either 0 s or 20 s, dramatically improved memory for sounds not frequently repeated independent of delay (Wright 1999b). These results show that by making the first two items familiar and not associated with any one list, these items generated little or no inhibition of retrieval memory for the last two items. When

the list position of the familiar items was exchanged, that is when the last two items were from the small (frequently repeated) set and were tested at the 20-s delay, memory of the first two list items increased to the similar accuracy level when all four items were from the large set. This latter result shows the powerful retroactive inhibition of the last items on retrieval memory for the first list items at these comparatively long retention delays. These effects cannot be due to encoding differences because the subjects have no way of knowing whether the last two items would be comparatively familiar or unfamiliar. Thus, it appears that retroactive inhibition is the major mechanism controlling auditory memory performance at long retention delays, whereas proactive inhibition is the major mechanism at short retention delays.

### Theoretical Implications of Visual and Auditory List Memory

There have been, to be sure, accounts other than inhibition to explain the shape of the serial position function. The popular and venerable dual-store models (e.g., modal model) claim that the recency effect represents short-term memory, which decays with time (e.g., Atkinson and Shiffrin 1968; Gillund and Shiffrin 1984; Haarmann and Usher 2001). But the monkey's auditory recency effect cannot represent short-term memory because a recency effect is not present initially; its later appearance is more like a long-term memory effect than a short-term memory effect. Other accounts of dynamically changing serial position functions have included temporal distinctiveness (e.g., Knoedler et al. 1999; Neath 1993a, b; Neath and Knoedler 1994) and storage versus retrieval strength (Bjork 2001). An item's temporal distinctiveness is thought to change with time like a receding row of telephone poles, with those in the distance less distinct than those closer by (Crowder and Neath 1991). But, as Bjork (2001) has pointed out, temporal distinctiveness cannot account for absolute (as opposed to relative) memory recovery, as shown by the visual primacy effect. To account for absolute recovery, Bjork (2001) proposed a storage-strength versus retrieval-strength model.

However, Bjork's (2001) model depends on learning with repetitions of the same list and would not apply to absolute recovery following a single presentation of each list, like those used to test the monkey's auditory (and visual) memory.

In conclusion, no explanation fares as well as inhibition to account for the auditory list-memory results. The evidence presented here is that retrieval failure underlies the monkey's auditory list memory. The auditory list-memory results show that proactive interference is strong just after an auditory list is presented, thereby causing retrieval failure and depressing recognition of the last items. Release from proactive inhibition causes an absolute increase in recency performance as the retention delay was lengthened. This is a substantial performance increase with retention delay and is counterintuitive because memory is commonly thought to decay with time. But as shown here, inhibition is dynamic and very different from decay.

## Definition

Locomotion refers to an organism's ability to translate itself from one place to another. This can be accomplished by active and passive means. It spans from the use of simple molecular machines to complex multi-organ systems acting in concert.

## Introduction

All organisms share a common ancestry along with a set of enduring biological directives reflecting their relatedness. Chief among these is the drive to persist by temporarily overcoming overwhelming physical and energetic obstacles. Organisms large and small, simple and complex, labor to survive long enough to produce viable offspring. To accomplish this, they evolved abilities to exploit beneficial resources and environments. Some eventually became able to seek new resources when local supplies became exhausted, transporting themselves to new environments.

Locomotion refers to an organism's ability to transport itself from one place to another. This is a task fraught with uncertainty and danger. Trading a known environment for an opportunity to find a

better one is risky at best. Many animals are particularly vulnerable during locomotion. Their available resources and attention become repurposed to the completion of this goal, making them particularly vulnerable to energy depletion and predation. Therefore, locomotion is a dangerous behavior not undertaken lightly. As such, it is often goal-oriented and used to increase fitness (e.g., securing nourishment, avoiding death/predation, reproduction). Because of the associated risks, many animals locomote in short bouts when approaching potentially dangerous environments. This allows them to sample their environment for dangers. The same animals, however, increase their bout durations when traveling back toward safety.

The evolutionary race for survival resulted in the production of highly diverse and complex sensory systems to probe environments and locomotor systems to convey animals to their destinations quickly and safely. How animals accomplish locomotion, and translate themselves from one place to another, depends on factors such as their evolutionary history, the physics of their environment, and the biological drive being satisfied.

Many animals living near the interface of distinct physical environments (e.g., land and water) evolved the ability to exploit multiple environments (e.g., one for sustenance and another for locomotion). For example, many insects and birds walk when foraging but switch to flight when traveling between feeding sites as a more energetically efficient form of locomotion. Crayfish and young lobsters walk on the bottom of springs and oceans but will swim away from predators using their powerful tails. Each distinct type of locomotion is made possible by dramatic feats of specialization in the animals' nervous system, skeleton, and musculature. While there are many examples of transition between environments over evolutionary time, most animals are specialized for locomotion through one physical niche throughout their lives. Those capable of locomotion through multiple environments must reconfigure their motor outputs to match the properties of each environment.

When studying simple processes, it is often possible to divide them into their components

and to dissect and understand the role of each part independent of the whole. Often, single chains of cause-and-effect hierarchies make easy work of understanding the process by sequentially dealing with each aspect of the whole. Animal locomotion defies this type of approach. Locomotion is not the final output of a chain of events; rather, it emerges from the tightly concerted interaction of numerous organismal systems (Alexander 2003). Thus, our compartmentalized approach to its study is more a reflection of our own limitations than a characteristic of the process we will now discuss.

Thus, while the following sections attempt to simplify our task by dealing with intuitive (dissectible) aspects of animal locomotion, the reader should remain aware that these separations are artificial and for our benefit. Furthermore, animal locomotion is not the product of a machine optimized for the performance of a task, but rather the survivable output of the cumulative history of a species. As such, it can only be fully understood in the context of an animal's life history challenges and of its inheritance passed down through evolution. We will next look at some of the challenges this behavior evolved to surmount before looking within organisms at its mechanics.

## Goals of Animal Locomotion

Why do animals move? As mentioned above, one of the primary drives common to all life forms is the directive to survive to reproduce. Thus, locomotion can be understood as an animal's attempt to improve the odds of this outcome. Some overarching goals driving locomotion include (i) avoiding death (self-preservation), (ii) finding mates (for sexually reproductive animals), and (iii) ensuring the survival of offspring. These are certainly not all the reasons why animals move. Additionally, some of these goals (e.g., self-preservation) include unique locomotor goals within them. For example, self-preservation includes escaping predators but also energy procurement. We will discuss some of these goals, as the (often competing) demands they place on animals have

driven the evolution of the distinct types of locomotion we appreciate in the natural world.

### Self-Preservation

Many distinct locomotor activities have the goal of maintaining an organism's viability. The exact locomotor behaviors depend on the animal, but minimally they involve (a) procuring and ingesting other organisms, (b) avoiding ingestion by other organisms, and (c) avoiding environmental risks (e.g., temperature extremes). Each of these tasks presents unique challenges that are often in conflict with one another. For example, searching for food often places animals at increased risk of predation.

Animals are unable to manufacture their own complex organic compounds for nutritional purposes (i.e., they are heterotrophic). Instead, they must obtain their nutrients by ingesting other organisms in their environment. Some animals, such as sponges, corals, and tunicates, are sessile and able to capture sufficient nutrients as they move past them. Even here, most of these animals have short motile stages where their larvae seek promising environments before becoming sessile. Large, complex animals are unable to reliably capture sufficient resources without investing energy to seek them out regularly.

Each vital locomotor activity often requires distinct neural specializations. Finding food (or mates) requires extreme feats of sensory detection involving computationally expensive specialized search strategies. For example, moths use a strategy called *casting* when following pheromone plumes in search of mates. Similarly, dogs tracking scents employ active sensing, sampling their environment at regular intervals. In both examples, sensory inputs are integrated over time to deduce the scent's source.

Locomotion during the search phase of mate or food procurement needs to be slow enough to allow the nervous system enough time to sample the environment and resolve (often tenuous) gradients. During this type of locomotion, sensory processing can be the rate limiting factor. Increasing the organism's investment in its sensory system can result in higher neural acuity, sampling speed, and resolution. However, this also carries

heavy energetic costs, which animals must balance with their needs.

While searching for food might be slow and involve large sections of the central nervous system acting in concert, avoiding predation is often more straightforward. During predator avoidance, an animal's reliance on its sensory system comes down to a single vital piece of information: locating the threat. This information is used to trigger often stereotypical escape behaviors that remove the animal from danger. Because escape speed is often the variable that separates life and death, nervous systems show adaptations that optimize the speed of these behaviors. These include:

- (a) Using as few cells as possible to sense and trigger the escape response (minimizing delay associated with synaptic communication).
- (b) Using electrical synapses whenever possible. Chemical synapses, while malleable and effective, are also the slowest (each adds at least 1–5 ms to signal conduction time). Therefore, many escape behaviors rely on a few, fast ( $<0.3$  ms), electrical synapses.
- (c) Using large diameter nerve fibers and myelination to maximize the impulse velocity.

There are many examples of escape behaviors making use of these neural optimizations. The Mauthner cell in fish and amphibians is a large neuron that makes extensive use of electrical synapses to produce fast escape responses. Similarly, large diameter neurons and/or electrical synapses also mediate the tail-flip escape response in crayfish, escape jet propulsion of squids, escape jumps in fruit flies, and more. Similarly, myelination of escape neurons in some copepod species allows these animals to perform faster, energetically efficient, escapes than they could perform otherwise.

Animals that succeed in consuming (and avoid being consumed by) other organisms are still faced with the task of surviving changing environmental parameters. The magnitude of this task varies significantly across species. For animals unable to regulate their temperature (i.e., ectotherms), or those living in harsh environments (e.g., deserts), the task might pose greater risk than predation or starvation. Because many

environmental parameters change between day and night, or across different seasons, animals often relocate to avoid environmental extremes. Locomotion in response to cyclical environmental fluctuations are responsible for many of the great animal migrations occurring across the world, from the daily vertical migrations of jellyfish in the ocean to the yearly migrations of the monarch butterfly in North America.

However, some environmental parameters change too fast for animals to successfully relocate once change is underway. Faced with this challenge, some animals initiate their locomotion before environmental variables begin to change. Nervous systems thus evolved internal (biological) clocks allowing them to predict and behave in anticipation of impending environmental changes. Accurately anticipating environmental variations is of paramount importance in survival. In addition to these predictive computations, animals often use environmental cues (e.g., photoperiod) to decide when to initiate their migrations.

### Finding and Securing Mates

Solitary organisms that rely exclusively on sexual reproduction must travel to find potential mates. Finding a mate can involve returning to a natal site or group (philopatry) or dispersing to new areas and populations (Greenwood 1980). Animals that disperse must seek out and find mates in isolation. For example, moths will orient to chemical signals (pheromones) to find a mate. However, philopatric animals often engage in group migrations which increase their odds of finding suitable mates. Examples include crabs, polychaete worms, salmon, and migratory birds. Regardless of their strategy, searching for mates often increases the chances of predation.

### Ensuring Offspring Survival

Following reproduction, animals must sometimes protect and feed their young until they are independent. Some animals travel to find a suitable place to rear their offspring and then to a place to forage for them. Emperor penguins, for example, can travel up to 500 km to forage for food to bring to their offspring.

## Molecular Motors

We discussed above some of the reasons why animals elect to translate themselves from one place to another. We now turn to how animals accomplish these feats. In this section we discuss the molecular motors powering all forms of animal locomotion (Schliwa and Woehlke 2003).

Cells maintain their shape by means of structural proteins polymerized into rods and tubes that form their cellular skeleton (cytoskeleton). To shuttle proteins and other payloads around, some proteins evolved the ability to use chemical energy (in the form of ATP) to walk their cargos along these cytoskeletal fibers. A key development in the evolution of animals came when these molecular motors (e.g., dynein and myosin) became harnessed not just to pull a cargo along a polymerized fiber but also to move these fibers against each other. This endowed these molecules with the ability to generate locomotion by stirring fibrous projections in the surrounding environment (e.g., flagella) or to reversibly reshape cells to produce locomotion (e.g., muscle contractions).

### Cilia and Flagella

Cilia and flagella are strictly the same cellular organ (henceforth flagella), although they are discerned by their length and number. Eukaryotic cells may have only a few ( $<10$ ) large flagella but may have thousands of cilia. While both prokaryotic and eukaryotic cells evolved flagella, and use them in locomotion, these organs are structurally distinct. Eukaryotic flagella are powered by dynein ATPase motors and have a cylinder (i.e., axoneme) containing two single microtubules surrounded by nine microtubule doublets (Woolley 2000). The entire assembly lies perpendicular to the cell surface and is surrounded by flexible extensions of the cell membrane. Many additional proteins, both in the flagella and at their base (called centrioles), are responsible for the generation and control of its motion. Movement at the base of these structures produces a wave that travels distally and can be either two or three dimensional. Unlike its eukaryotic counterpart, prokaryotic flagella are composed of a hollow

cylinder made of flagellin. At the base of these flagella, a small protein assembly creates an electric motor driven by atomic currents derived from ( $\text{Na}^+$  or  $\text{H}^+$ ) ions entering the cell.

Cells typically have only a few long flagella but may have thousands of short cilia. Whereas flagella generate propulsion by beating in a continuous corkscrew fashion, cilia generate metachronal waves during which their action is divided into the power-generating stroke phase and the recovery phase when there is no propulsion generated. These differences may reflect their favored use. Flagella are well suited for generating large, propulsive forces (e.g., spermatozoid's flagellum), but cilia can be differentially controlled within a single cell, resulting in highly precise movements.

For billions of years, bacteria, archaea, and later eukaryotes used flagella to seek out viable environments. These molecular propellers and oars continue to translate these microorganisms to hospitable environments. In animals, flagella and cilia fulfill a myriad of roles: from propelling sperm and moving oocytes along to removing debris in the respiratory system or detecting light, sound, and gravity. The rise of multicellular organisms, and their consequent increase in size, weight, and drag, reduced the effectiveness of these motors due to their ever-heavier payloads. Thus, as animals grew in size and complexity, they evolved alternative means for propulsion better suited to their larger scales. However, some small gastropod snails (and even some not-so-small sea slugs) remain able to achieve propulsion purely by the action of their cilia. They accomplish this by sliding over their mucus secretion. However, unlike their unicellular counterparts, the beating of cilia in these animals is under neural control.

### Myosin II

To achieve propulsion, cilia and flagella must be exposed to the environment. A second type of molecular motor evolved from the novel rearrangement of core proteins. It allowed single-celled organisms, and eventually multicellular animals, to move through their environment by causing entire cells to act as motors.

Myosin heavy chain II is a molecule capable of transforming chemical energy (ATP) into mechanical energy (Rayment et al. 1993). Myosin is comprised of two light chains and two heavy chains that combine to give rise to the molecule's characteristic two heads, neck, and tail domains. The N-terminal halves of the heavy chain give rise to the globular heads, while the tail of myosin is assembled from the C-terminal halves. The tails of the molecule can polymerize together to form a filamentous backbone lined with the globular heads along its surface. Each head of myosin II consists of a motor domain that binds to the thin filament actin when allowed to hydrolyze ATP. Myosin successively binds, deforms, and releases an ordered lattice of actin proteins. These additively transfer the combined mechanical deformation of all myosin molecules to effectors such as membranes, tendons, and skeletons, thereby generating propulsion.

Myosin II predates animals and is found in amoeba and fungi, as well as in primitive animals lacking muscles such as sponges and cnidarians. Amoebas are large unicellular organisms that locomote through the protrusion and retraction of cellular pseudopodia and rely on the activity of the actin-myosin II complex. Besides locomotion, myosin also functions in cell division, migration, and shape.

## Cellular Motors

### Muscles

Cilia and flagella are feats of evolution, allowing (mostly) small unicellular organisms to move effectively in their native aqueous environments. To be propulsive, these structures must act at the interface of the animal and its environment. For mostly sessile animals (e.g., sponges), flagella function by propelling food particles into digestive cavities. However, as many organisms grow in size and cell numbers, their surface area to volume ratio rapidly drops. Under these conditions, fluid flow changes from laminar to turbulent (see Reynolds numbers below), reducing the propulsive effectiveness of flagella.

Unlike flagella, myosin II acts within cells. Their numbers and effective forces can therefore scale with the volume of cells, rather than just with their surface area (i.e., flagella). This allows these molecules to generate forces strong enough for large cells to deform (and even divide), allowing them to interact physically with other cells and their environment to generate propulsion.

One limitation to the use of myosin in propulsion is the necessity to effectively transfer these large forces to the environment without structurally compromising the cells themselves in the process. This challenge becomes significant in multicellular animals, where myosin and actin allow many cells, even those buried deep within an animal, to become motors and generate combined forces far greater than those previously possible. When the structural elements responsible for transferring these forces are absent (e.g., loss of dystrophin in Duchenne muscular dystrophy), the powerful forces generated by the actomyosin complex are strong enough to rip muscle cells apart (Nowak and Davies 2004). Arguably, when properly harnessed, the versatility and scalability of the actomyosin complex can give rise to the enormous diversity of animal forms, sizes, and locomotion we observe in the animal kingdom.

### Skeletal Muscle Structure

In vertebrates, three types of muscles are recognizable by their structure, their function, and the forces they generate. Skeletal muscles are responsible for locomotion and are discussed below (Lieber 2002); cardiac muscles are structurally similar to skeletal muscle but are capable of myogenic contractions (i.e., able to initiate contractions autonomously); and smooth muscles are also capable of myogenic contractions but possess unique myosin organization (see below). We will restrict our discussion to skeletal muscles as they are responsible for producing locomotion.

In vertebrate skeletal muscles, each myosin filament is surrounded by six actin filaments. Actin filaments are fixed to a z-disk (comprised of a vast array of interlinked proteins and fibers) at one end. The ends of the actin filaments not bound to the z-disk bind to one of the distal ends of the centrally located myosin fibers. The sarcomere is

the smallest contractile unit of a muscle, and the z-disks themselves are ultimately responsible for transferring the force generated by actin and myosin within the sarcomere. Sarcomeres are aligned in series (end-to-end) within elongated threads called myofibrils. In humans, myofibrils can be up to 1 cm in length. Myofibrils are like threads in a rope; they are bundled together to form thicker and longer fascicles.

The head of the myosin molecule has two binding sites (one for ATP and one for actin). When ATP binds to a myosin head, it causes it to release an actin filament. Following the release of the previously bound actin filament, myosin hydrolyzes the bound ATP to ADP + P<sub>i</sub> and uses the energy released to change conformation and weakly bind to an actin filament. On the actin filament, two free Ca<sup>2+</sup> ions bind to troponin, causing the protein tropomyosin to slide and allowing actin filaments to fully bind to the myosin head. Finally, myosin releases the inorganic phosphate and initiates the power stroke in which it changes conformation and slides the actin filament toward the center of the sarcomere, shortening the sarcomere as a consequence. Myosin then releases the bound ADP and remains in this (rigor) state until a new ATP binds to its free site, restarting the contractile cycle.

Animals can alter their muscle architecture in a variety of ways to generate different types of forces. At the ultrastructural level, long series of sarcomeres activated simultaneously generate quick muscle shortening and allow animals to generate fast motion. Conversely, arrangements of sarcomeres in parallel allow the generation of large powerful forces. In vertebrates, myosin can be found polymerized into thick filaments with their long axes aligned with the fiber and their globular heads pointing away from a bare center zone (e.g., striated muscle). Alternatively, myosin can be at an angle to the filaments' long axis with their globular heads, covering the whole length of the filament. This arrangement is found in smooth muscle.

Invertebrate muscles display even more diversity. Many species alter their myosin diameter, length, and myosin-to-actin ratio even within a single muscle cell. A type of invertebrate muscles

termed “asynchronous muscles,” found in flying insects, are capable of contraction rates an order of magnitude faster than is possible through other muscles. Used to power flight, these muscles are driven by mechanical stretch rather than neural stimulation.

### **Additional Function of Muscles during Locomotion**

The most intuitive role for muscles during locomotion is that of generating propulsive force. Besides acting as motors, muscles can perform other functions during locomotion (Dickinson et al. 2000). For example, muscles can stiffen to become force transmitters rather than generators. This “strut” function allows the optimal transmission of force from multiple muscles into a single effector organ. For example, in fish that use their caudal fin for propulsion, posterior muscles become stiff and act as struts to convey anteriorly generated forces to the tail. Once these forces pass, the muscles resume their propulsive role to generate force by contracting, then conveyed to the (still stiff) posterior muscles of the tail.

Many invertebrate muscles possess a myosin binding protein (i.e., paramyosin), which allows them to display a property called “catch” in which they can maintain force in the absence of actomyosin activity. The best-known examples of catch muscle fibers are those of bivalve mollusks, which they use to hold their shells tightly closed for long periods of time.

Another role muscles can perform during locomotion is that of brakes. During running, extensor muscles in the legs of cockroaches do not act to generate power, but rather to slow the velocity of the swing phase of the motion. This type of activity provides a metabolically inexpensive way to slow down locomotion.

### **Muscle Contraction**

Contractions are initiated when calcium ions are released from intracellular storage compartments and bind troponin. In order for the many sarcomeres in a muscle to act in synchrony, the release and removal of calcium ions must be under precise control. As mentioned above, muscles that achieve this endogenously are known as

myogenic. Cardiac, arterial, and intestinal muscles are examples of myogenic tissues. It is likely that the ancestral muscle was similarly myogenic and able to independently respond to environmental stimuli. Myogenic contractions work well for (relatively) independent organs such as arteries or guts (Horowitz et al. 1996). While hormonally regulated, these organs function in partial autonomy. However, myogenic contractions are not well suited for most forms of animal locomotion, where different muscles acting remotely from one another must achieve precise timing to produce accurate locomotor patterns. For these complex muscular ensembles, endogenous or reflexive activation could not produce the fast, reliable, and diverse array of activities associated with locomotion. Therefore, around the same time muscles evolved, a second type of specialized excitable tissue evolved which could coordinate muscle activity. These cells could detect meaningful environmental information, compute appropriate responses, and mount an appropriate organismal activity by synchronizing patterns of muscular activation. They gave rise to the nervous system.

### **Neural Control of Locomotion**

The movements of charged atoms (i.e., ionic currents) are important drivers of prokaryotic flagella and eukaryotic muscular contractions. In muscles, the magnitude and speed of intracellular calcium release allow quick and synchronous activation of millions of myosin molecules throughout these large cells. Around the same time as muscle cells were getting their evolutionary start, a second type of specialized cell evolved to also harness ionic currents to communicate distant parts of large multicellular organisms. Neurons are specialized cells that can detect and integrate environmental changes as well as select and elicit adaptive patterns of muscular activity.

Neurons can communicate with one another (and with muscles) using chemical molecules released across intercellular approximations called (chemical) synapses (Jessell and Kandel 1993). Chemical synapses are by far the most

common way by which neurons communicate. Because of the large number of proteins involved in this type of communication, they lend themselves to the modification and modulation characteristic of learning. Most forms of proactive locomotion, that is, locomotion initiated in response to internal drives, rely primarily on chemical synapses coordinating the activation of different muscle groups.

A second form of neuronal communication is the electrical synapse or gap junction (Bennett 1997). Gap junctions rely on proteins creating physical channels between adjacent neurons. These allow ions and small molecules to travel freely between cells. By connecting the cytoplasm of two cells electrically, gap junctions are responsible for the fastest form of cell-to-cell communication. This speed, however, comes at the cost of plasticity. Electrical synapses lack the degree of modulation that chemical synapses champion. However, the velocity of these synapses makes them ideal for synchronizing different cells and for driving reactive locomotion or locomotion that is initiated in response to external perturbations. For example, electrical synapses are responsible for coordinating many escape behaviors in the animal kingdom such as the C-star escape in fish or the tailflip of crayfish.

A third way in which neurons control locomotion is by the action of molecules released into systemic circulation (Harris-Warrick and Marder 1991). The release of chemical modulators by neurons is a way of altering the function of multiple and remote locomotor systems in an organism. Whereas diffusion of chemicals across an organism makes this the slowest form of neural control, its global effects (simultaneously reaching multiple tissues), coupled with its combinatorial potential (using multiple signaling molecules), make this one of the most diverse and robust ways of generating behavioral diversity. For example, the simple stomatogastric ganglion driving mastication in crustaceans is comprised of about 30 neurons interconnected by electrical and chemical synapses. Although the number of neurons may seem small, the patterns of muscular activation this network can produce are vastly increased by an even larger number of modulatory

substances, which can act singly or in combination to produce many behavioral patterns.

### Central Pattern Generators

Whether it is the crawling of a worm, or the swimming of a whale, successful locomotion relies on the appropriate pattern of muscular activation, which must be initiated and maintained throughout the duration of the behavior. This necessitates synchronization of distant muscles, which must be contracted and relaxed in precisely the correct order and with the appropriate duration and intensity. In addition, sensory information about changing environmental and internal conditions must be allowed to modify the initial motor output. For example, a strong gust of wind, a change in terrain inclination, or a misstep could prevent the completion of a locomotor goal unless the animal used sensory feedback to correct motor outputs to match new available information. In the next section, we discuss sensory modulation of locomotion, but first we will consider the generation of motor outputs.

Most forms of animal locomotion rely on the rhythmic activation of groups of muscles. These cyclical patterns of activity are often the product of specialized neural tissues dedicated to the production of these rhythms. They are known as central pattern generators (CPGs), and they are capable of producing rhythmic outputs in the absence of rhythmic inputs (Marder and Bucher 2001). Extensive work on cats demonstrated that the mammalian spinal cord houses CPGs for the production of walking and running. Similar central rhythmic centers have been identified across taxa, including nematodes and jellyfish.

Motor patterns are usually produced by one or several cells, which act as pacemakers for the rhythm. Pacemakers can consist of a single rhythmically active neuron, a pair of mutually inhibiting neurons, or a group of three or more cells. Although CPGs do not require inputs to generate an output, sensory feedback is crucial for modifying outputs and obtaining rhythms that reflect the changing needs of an animal. For this reason, rhythms recorded from isolated nervous systems (termed “fictive”) generally match rhythms observed in intact animals only partially.

In the absence of sensory feedback, rhythms tend to be faster and less variable than those recorded in intact preparations. The importance of sensory feedback to modulate motor output is exemplified in box jellies. These animals, among the simplest to possess nervous systems, use CPGs to produce locomotion. Nevertheless, the activity of their CPGs is modulated by input from rudimentary sensory organs (eyes), which help the animal steer their locomotion.

### **Locomotor Gaits**

Simple pattern generators such as the jellyfish's may be restricted to the generation of one or, at most, a few patterns of activity. This places limits on the behavioral repertoire they are able to produce. As animals increased their number of neurons, the number of possible synaptic connections between them grew exponentially. Increased interconnectivity permitted finer modulation of motor outputs and led to the evolution of alternative motor circuits animals could now select between. The neural networks responsible for these distinct programs could be independent or partially overlapping. Many of these circuits are highly conserved between species, and only minor modifications are needed to produce profound changes in outputs. In the case of distinct locomotor outputs, these are referred to as gaits (Alexander 1989).

The term gait is historically associated with the patterns of leg movements in pedestrian locomotion on land. Work pioneered by Eadweard Muybridge and his stop motion photography in 1878 allowed the study of the patterns of limb movements in freely moving animals. The study of animal locomotion has since expanded from animals walking on land to all animals (limbed or limbless) moving in every kind of environment by means of rhythmic movements. Locomotion researchers modified the usage of "gait" to include other types of locomotion. In general, two patterns of animal locomotion are considered to be distinct gaits if their production represents the output of nonidentical neural circuits. Animals thus may produce flying, swimming, crawling, walking, burrowing gaits, etc.

The production and selection of different gaits is associated with the distinct energetic costs of locomotion in different environments or speed ranges. For example, a person on an accelerating treadmill can increase their pace as the treadmill speeds up. However, beyond roughly 2 m/s, most people become unable to keep pace and are forced to switch from walking to running. This transition occurs at the point where walking faster would consume more energy than running slow. Walking and running gaits are optimized to minimize energy expenditure for a particular range of velocities. We discuss the energetics of locomotion in a later section.

While the transition between walking and running might be subtle and occurs within the same environment (on land), some gait transitions are more dramatic and involve different environments. For example, crawling and swimming involve the activity of the same muscles, but using distinct patterns of activity. These patterns of muscle activity involve different pattern generators and often rely on distinct sensory feedback. The ability to appropriately select and transition between distinct motor patterns is of paramount importance to survival. For many animals, getting this transition wrong once spells demise. Because of this, the mechanisms employed to effect these transitions tend to be highly conserved across evolution. For example, leeches and nematodes are evolutionary distant animals that use the signaling amines dopamine and serotonin to trigger transitions from swimming to crawling (dopamine) and vice versa (serotonin). Dopamine is an ancient molecule universally used to modulate locomotion. Loss of dopamine in Parkinson's disease, or through other insults, results in the inability to initiate locomotor patterns in worms just as much as it does in humans. Natural selection does not act on all processes equally. While the genes involved in the synthesis and use of signaling molecules are highly conserved across taxa, genes coding the receptors for these molecules have been free to diverge and increase in number. They are key contributors to the diversity of locomotor programs we see in the natural world.

### Sensory Feedback

The production of meaningful locomotion depends on an animal's ability to monitor (a) changes on its environment, (b) the position of its limbs during the performance of the behavior, and (c) its changing orientation and position with respect to its intended trajectory (Ausborn et al. 2009). Higher-order sensory systems, such as the olfactory, visual, and auditory systems, modulate the direction and speed of locomotion. These are instrumental in achieving the locomotor goal of translating an animal to its destination. At a more basic level, internal organs such as the inner ear (or statocysts in invertebrates) allow animals to maintain appropriate body orientation during the performance of locomotion. Lastly, proprioceptor organs distributed throughout the organism provide ongoing feedback to central motor centers that allow the continuous adjustment of motor outputs. It is through the continuous and combined inputs of these sensory streams that locomotion becomes relevant and meaningful to the survival of the organism.

### Physical Variables Influencing Locomotion

Animals adapted to move in every niche afforded by our planet. These include environments with physical properties that place unique demands or constraints on the strategies available. For example, demands faced in aquatic and aerial locomotion are distinct from those encountered during terrestrial or subterranean locomotion.

#### Environment

Our planet is lush with diverse environments animals can exploit in their quest to survive and reproduce. The seas were the first biotic environment and remain home to millions of animal species. Locomotion through a fluid (liquid or gaseous) is dominated by the friction and inertia experienced by an animal as it collides with the molecules in the fluid around it (Sfakiotakis et al. 1999). To minimize resistive (drag) forces experienced while swimming (or flying), animals often

evolved hydrodynamic (or aerodynamic) shapes that reduce the number and intensity of collisions with the particles making up their environment. In physical terms, the primary distinction between aquatic and aerial locomotion resides in the relative density of animals to their environment. Animals that are denser than their environment sink and must continually spend energy to remain air- or waterborne. Both aerial and aquatic animals often possess adaptations that allow them to mitigate the effects of this differential density. For example, birds have hollow bones that considerably reduce their weight, while most bony fish have swim bladders that allow them to control buoyancy without having to swim continuously. These adaptations reduce the energy required to maintain the animal within its locomotor substrate.

The familiar shape and locomotor strategies of swimming animals evidence their commitment to a single physical environment (Gleiss et al. 2011). The similarities between aquatic and aerial environments allowed many birds to become apt swimmers without compromising their flight abilities.

Subterranean locomotion places unique physical demands on animals. We define subterranean locomotion as locomotion through solids such as soils, sands, or even other organisms. These environments are characterized as being overwhelmingly dominated by resistive forces and the absence of inertia. Although mostly understudied, burrowing is one of the most commonly used forms of animal locomotion (Gans 1973).

Like swimming and flying, the physical demands that burrowing places on animals have resulted in the evolution of an optimal burrowing shape adopted by most animals that burrow regularly: the vermiform or wormlike shape. Like fish and birds, most worms are bilaterally symmetrical. However, because their density is often lower than that of their environment, worms often adopt a cylindrical shape that allows them to exert forces equally well in every direction. For example, peristaltic waves allow worms to maximize propulsion by generating thrust in every direction. For burrowing animals, the relative density of the media determines the optimal burrowing strategy.

Swimming and burrowing are modes of locomotion in which animals inhabit and locomote through a single physical environment. However, many animals evolved the ability to exploit the interphase between distinct physical environments as a way to reduce the energetic cost of locomotion. Terrestrial and benthic animals take advantage of the differences between different physical environments to effectively locomote at their interface. For example, walking animals exploit the resistive differences between soil and air, using the high resistance in the ground to generate propulsion and the lower resistance of the air to move large, heavy payloads. Walking evolved multiple times in aquatic and terrestrial animals. Tetrapod walking first evolved in sarcopterygian fishes. Arthropods, including crustaceans and insects, produced some of the most sophisticated walkers nature has to offer. Even apt swimmers like cephalopods can produce bipedal walking under certain conditions.

Birds and insects are the most proficient and prolific users of multiple physical environments. Many species spend considerable time locomoting in two or more distinct media. Locomotion in multiple physical environments poses distinct challenges depending on the environments in question. For example, as discussed above, aquatic and aerial locomotion share some similar challenges that allow many flying animals to swim effectively using the same machinery they use for flight. However, there are limits to this overlap. Other forms of locomotion are considerably less synergistic. For example, the demands placed by walking and flying are so different that animals must maintain distinct neuromuscular and skeletal machineries dedicated to each type of locomotion. The high energetic costs of maintaining two independent locomotor systems result in animals dedicating more resources to one form of locomotion over another. As such, many birds are better flyers than they are walkers or swimmers. Alternatively, there are examples of birds where walking or swimming is preferred over flying; however this usually leads to the loss of flight (e.g., ostriches and penguins). An alternative to this type of compromise or commitment is found in arthropods. Insects often have

complex life histories that allow them to sequentially specialize for distinct forms of locomotion during different life stages. For example, dragonfly larvae are voracious aquatic predators capable of walking, swimming, and even jet propulsion, while their adult form is one of the most effective flying hunters in nature. Therefore, dragonflies and other insects can exploit distinct environments by using them during different life stages. Of course, before some swimming larvae can become an aerial adult, they must invest a considerable amount of energy and time undergoing the process of metamorphosis with all the dangers and costs associated with it.

The physical properties on an environment clearly place unique challenges and opportunities for animal locomotion. We now discuss the challenges and opportunities associated with the animals themselves and with their locomotor strategies.

### Stability and Maneuverability

Stability refers to the ability of a system to withstand perturbations that would bring it away from equilibrium (Full et al. 2002). For standing animals, *static stability* is dictated by the interaction between an animal's center of mass and its base of support. We will use the analogy of a painter's folding ladder to visualize how this interaction works. In the opened position (with the legs placed well apart), the ladder is in its most stable configuration. Considerable force can be applied to it before this stability is compromised. This is because the ladder's center of mass lies well within a base of support. As long as destabilizing forces do not move the center of mass outside of their base of support, the ladder will remain stable. If the legs of the ladder are brought closer together, the base of support decreases in size, and the ladder becomes less (stable) able to withstand perturbations. Most ladders have rectangular bases of support (wider than long). Therefore, ladders can withstand greater perturbations in one direction (it is easier to tip a ladder sideways than forward or backward). Animals follow the same rules of stability as the ladder in the analogy above. For example, standing quadrupeds with narrow bases of support (e.g., a horse) are less stable than animals with wider base of support.

One of the most consequential properties of stability is that it is independent of the source of the perturbations. A system that is highly stable will resist environmental perturbations (e.g., wind) as much as they will resist perturbations they themselves cause (e.g., locomotion). Because of this, animals must carefully balance an equation where on one hand they have their ability to withstand unwanted perturbations and on the other is their ability to disrupt their stability to achieve locomotion. One way by which many animals solve this problem is by altering their posture depending on their changing needs. For example, many animals adopt a sprawled stance when engaged in withstanding environmental perturbations and a more upright stance during locomotion.

Once locomotion is initiated, stability is not discarded. Instead, the challenge increases in complexity as it must be achieved for a body in motion. This is termed *dynamic stability*, and it pertains to the ability of a moving body to withstand perturbations. Like the static stability discussed above, an animal's dynamic stability is realized as a compromise between competing needs, namely, the animal's need to resist unwanted perturbation versus its need to produce quick, intentional disruptions such as turning, dodging, abrupt breaks, etc. (e.g., maneuverability).

It is easy to underestimate the challenge that animals face to achieve both high stability and maneuverability. On first approach, animal locomotion can seem simple: an animal exerts force on its environment and produces acceleration (locomotion) in the opposite direction. However, this bears little resemblance to reality. Locomotion in most animals is accomplished by the oscillation of bodies or appendages that exert nonlinear forces on their environment. Indeed, if animal locomotion consisted of straight, steady-state motion, one would not expect to see animals invest in the large number of muscles, neurons, or appendages they often have for the purpose of propulsion. The heavy investment in the generation and control of locomotion can only be understood in light of both the important role of locomotion in survival and in the unpredictable

nature of the external and internal perturbations that challenge its completion.

### Energetics of Locomotion

Locomotion in animals requires the expenditure of large amounts of energy (Schmidt-Nielsen 1972). Due to its energetic cost and incurred risks, animals do not generally engage in locomotion unless there is a physiological need being served that justifies the expenditure. When animals do move, only part of the energy spent is transformed into propulsion. A significant fraction of the energy spent in locomotion is converted into unproductive motion or lost entirely to the environment.

The locomotor strategy employed by animals depends on the most energy-efficient options available in a given environment. Walking animals use the high friction conditions of the ground to generate propulsion but must minimize ground contact to not lose energy to this very friction. For example, at low speeds, walking animals use an inverted pendulum strategy where the body mass moves up over each leg in a motion reminiscent of an inverted pendulum. Part of the energy spent in propulsion is transformed into forward displacement, while part of it is saved as potential energy as the body moves up. The potential energy is then harvested during the second part of the stance phase when the body falls forward toward the next step. The maximal velocity walking animals can achieve is constrained by the earth's gravity, as this force field powers the second half of each step. For animals that are able to temporarily generate accelerations greater than that of the earth's gravity, a second type of motor gait becomes available. At faster speeds, these animals transition to a form of locomotion called running (or hopping, trotting). Here, motion by the center of mass resembles a pogo stick. All muscles are used to generate forward and upward propulsion (which might lead to an aerial phase). During the second part of the stride (as an animal accelerates downward), tendons, muscles, and ligaments absorb vertical forces and store them as elastic energy, ready to propel the first part of the next stride. The use of elastic body components to store energy is also in use in the horizontal plane. Many

animals such as lizards and crabs have sprawled postures that generate significant lateral motion while walking. The energy spent in lateral displacement is stored and partially recovered during successive steps. For slower walkers, this strategy is useful in more than one way. It also enhances stability by allowing the animal to absorb and use disruptive forces such as those experienced when pushed. Because these strategies are based on physical constraints posed by the environment, they are observed in most walking animals (Full and Koditschek 1999).

The energy-saving or recovering strategies described above are not only used by walkers but also by swimmers and fliers. As they push against a fluid (air or water), these animals impart forces on their environment, causing it to move in vortices. Many animals ranging from insects to salps, fish, and birds control the shape and distribution of these vortices to recover part of the energy lost in their generation. For example, generation of tightly packed vortex rings allows swimmers higher velocities and efficiencies. Similarly, flying insects generate lift with their wings in large part due to the vortices created above at the leading edges of their wings.

### Size and Reynolds Numbers

Organisms locomoting through fluids constantly crash with the particles in their surrounding media. They therefore must spend energy to move the fluid out of their way, and they must overcome the internal friction of the fluid (i.e., its viscosity). Osborne Reynolds determined that flow patterns in fluids could be predicted by the ratio of the inertial forces over the viscous forces present in a system (Reynolds 1883). This relationship turned out to predict a great deal of natural phenomena from flow through pipes to the locomotor strategies available to animals. The ratio of these forces (Reynolds number) is a widely used, dimensionless number. For animals (solids) moving through a fluid, the Reynolds number ( $Re$ ) can be calculated as the product of the density of the media ( $\rho$ ), the velocity of the animal ( $V$ ), its length factor ( $L$ ), and the inverse of the viscosity ( $\mu$ ) of the medium:  $Re = (\rho VL)/\mu$ .

For biological systems, this number ranges from  $\sim 10^{-6}$  (bacteria) to  $\sim 10^{14}$  (whales).

At high Reynolds numbers, inertial forces dominate animal locomotion. However, as the fluid viscosity increases ( $Re = 1$ ), viscous forces dominate, and animals produce purely laminar patterns of flow over their bodies. Above  $Re = 40$ , turbulence develops in the wake of the animal (see above). Beyond  $Re = 10^6$ , the cost of overcoming turbulence to increase speed becomes challenging. Animals can push the velocity at which turbulence becomes insurmountable by streamlining their shape. This is a widely used strategy by larger swimming and flying animals (e.g., fish, birds), but that would present no advantage for small swimmers operating in the absence of turbulence (e.g., bacteria). Many animals exist within Reynolds numbers characterized by both viscous and inertial components (e.g., the nematode, *C. elegans*). Others can span Reynolds numbers posing distinct physical demands as they grow in size or transition between different environments.

## Survey of Locomotor Forms

Animals adapted distinct forms of locomotion to best suit their physical environment and to accomplish the goals of self-preservation, finding and securing mates, and ensuring the survival of offspring. We discuss a few examples of the numerous types of locomotion that animals use to achieve these goals relative to their physical environments: aquatic, terrestrial, and aerial (Alexander 2003).

### Aquatic Locomotion

Aquatic environments lend themselves to several types of locomotion, from walking and swimming to sailing and jet propulsion.

**Walking** is accomplished by the cyclical motion of body appendages against a solid substrate. Many aquatic species evolved the machinery required for this type of locomotion. Because walking entails generating force against a solid substrate, most walking is performed using rigid limbs (e.g., arthropods and some fish). Some

animals, however, evolved the ability to walk using different means. Echinoderms such as starfish walk by means of tube feet, which rely on a water vascular system to inflate and deflate them during locomotion. Nudibranch sea slugs and other mollusks walk by means of their foot cilia, and some octopus use their arms to walk on the ocean floor.

**Burrowing** is a form of locomotion that takes place through solid media. Many aquatic species tunnel through the benthos using peristaltic waves of body contractions. Most of these animals developed vermiform (wormlike) shapes. Examples of this type of animal are nematodes and annelids. Their locomotion usually relies on the presence of a hydrostatic skeleton capable of precise rhythmic deformations. There are, however, many burrowing species that rely on other means for burrowing. For example, bivalves use their muscular foot to dig themselves into the substratum.

**Swimming by undulation** is one of the most commonly used forms of aquatic locomotion. Animals across taxa, from platyhelminths to mollusks and annelids, nematodes, arthropods, and chordates, evolved the ability to move through water by undulations generated along the longitudinal axis of their bodies. These undulations can be lateral, as in the case of most fish and reptiles, or dorsoventral, as in the case of marine mammals like dolphin, whales, or seals (Sfakiotakis et al. 1999).

**Swimming with appendages** is the main manner by which organisms inhabiting the low Reynolds number space generate thrust (Purcell 2014). When viscous forces dominate locomotion, symmetrical (reciprocal) forces such as body undulations become ineffectual. Many small animals rely on nonreciprocal motion generated by flagella or on swimming appendages that evolved multiple times in most animal groups. Appendages generate propulsion through nonsymmetrical motion that is divided into the power-generating phase (when interaction with the medium is maximized) and the recovery phase (when interaction with the medium is minimized). Many cartilaginous fish, arthropods, and other animals locomote through water (and other environments) using

their appendages. Examples of swimming appendages include fins (e.g., fish), swimmerets (e.g., krill), wings (e.g., penguins), and legs (e.g., cormorants).

**Sailing** is a passive form of locomotion used by some aquatic animals. Cnidarians are among the most prolific sailors with several species taking to this form of locomotion. For example, the by-the-wind sailors form disks that dwell on the water surface on top of which a triangular fin sits able to harness wind force in locomotion. Another sailing cnidarian is the Portuguese man-of-war, which, unlike the permanent stiff sail of the by-the-wind sailor, has an inflatable gas-filled sail it can use to travel.

Just like cnidarians are able to exploit the water-air interface for locomotion, many animals exploit the benthos (the water-ground interface) to the same end. Like swimming, benthic locomotion can be achieved by body undulations or by the motion of specialized appendages.

**Jet propulsion** evolved convergently in many aquatic animals as a mechanism for evading predators and approaching prey. The most well-known example of jet propulsion comes from jellyfish, which propel themselves by ejecting water from their oral cavity. Cephalopods (e.g., squid and octopus) draw water into their mantle cavity under low pressure; water is quickly expelled through the siphon under high pressure. The generated force propels the animal in the opposite direction, which can be controlled by movements of the siphon. Additional examples of jet propulsion come from scallops and dragonfly larvae, which are capable of jet propulsion by using their rectal chamber to hold and expel water. Jet propulsion is limited by the volume of water used for reaction mass (which is dependent on the animal's cavity size). Many coleoids adapted undulatory fins for fish-like locomotion.

## Terrestrial Locomotion

Many animal orders transitioned from aquatic to terrestrial environments. Whereas some locomotor approaches used in aquatic environments are ineffective on land (e.g., jet propulsion and swimming), many approaches that first evolved in aquatic environments remain effective.

**Burrowing** is a widely used locomotor strategy for many animals including nematodes, annelids, arthropods, and vertebrates.

**Walking** is one of the most effective forms on locomotion on land. Terrestrial environments offered walkers decreased drag and buoyancy compared to aquatic walking. This increased their ability to generate greater propulsive forces (due to their increased effective weight) and to experience less resistance. The result of these improved conditions was the evolution of the fastest forms of pedestrian locomotion for both vertebrates and arthropods.

**Crawling** is mostly performed by limbless animals that produce either axial bending to produce propulsive forces as in the case of snakes and some fishes or by peristaltic waves as in the case of many arthropod larvae.

**Jumping** or hopping involves the simultaneous retraction or extension of the hind legs, followed by an aerial phase of movement. Jumping is the dominant mode of terrestrial locomotion in frogs, and it is also found among mammals and arthropods. Whereas most animals use muscular contractions to power their jumps, some arthropods evolved additional mechanisms, enabling them to attain greater accelerations and improved jumping performances. For example, jumping spiders use hemolymph pressure to extend their legs, and planthopper insects evolved biological gears to power their ballistic jumps.

Most terrestrial animals locomote on, or through, the ground; however, some terrestrial animals evolved the ability to locomote through the air.

### Aerial Locomotion

True flight has evolved independently at least seven times among insects, birds, and mammals. By sheer number of species, and flight modes, insects are the most prolific aerial group.

**Active flight** refers to flight produced by muscular exertion of an animal's flight machinery. Insects, the undisputed champions of this form of locomotion, began flying during the Carboniferous (~350 mya). In insects, flight can be produced by the action of direct, or indirect, muscles. With *direct flight*, muscles attach directly to the

wings. Examples of this arrangement are dragonflies and mayflies. Most insects, however, use *indirect flight*. Here, flight muscles attach not to the wing, but rather to the thoracic skeleton. Compressions of the thoracic cavity result in the (indirect) movement of the attached wings. In birds, active flight dates back to the earliest avian ancestors (e.g., Archaeopteryx) some 150 mya and is responsible for the great success and diversity of this group. Among mammals, bats alone evolved the ability for powered flight. Unique among animals, squids are capable of flight by means of rocket propulsion. This involves the generation of lift by means of forceful ejection of water from their mantle cavity during flight.

**Gliding** refers to the use of gravity to power forward locomotion. By harnessing and controlling the drag forces experienced during free fall, gliding animals travel with only minimal energy expenditure. Birds are the champions of this type of locomotion, with albatrosses being able to harvest up to 20 times in horizontal displacement what it invests in falling vertically. Gliding also occurs among mammals (e.g., flying squirrels), amphibians (e.g., gliding frogs), reptiles (e.g., geckos), fish (e.g., flying fish), and mollusks (e.g., squid).

**Ballooning** refers to the passive aerial dispersal of animals using silk threads to harness the wind. This process is best understood in spiders that use it to disperse following hatching, but it also takes place among mites and some insect larvae.

## Locus

Elizabeth K. Mallott  
Department of Anthropology, Northwestern  
University, Evanston, IL, USA

## Synonyms

[Gene locus](#)

## Definition

Location on a chromosome of the DNA sequence for a gene.

## Introduction

A locus is the physical location of a gene on a chromosome. There may be one or more alleles at a single gene locus. In diploid organisms, there are two copies of each locus on the autosomal chromosomes. An individual can have two copies of the same allele at a locus and have a homozygous genotype or have two different alleles at a locus and have a heterozygous genotype.

## Pleiotropy and Complex Traits

Pleiotropy occurs when a gene at a single locus effects multiple traits. For example, one allele of the *tb1* gene in corn not only causes the plant to have multiple branches instead of a single stalk, but also results in increased numbers of leaves, smaller leaves, and smaller ears of corn (Losos et al. 2017). In contrast, complex traits are those that are influenced by multiple genes at multiple loci.

## Recombination and Linkage Disequilibrium

The law of independent assortment states that individual genes assort independently during gamete formation, so that the allele a gamete receives for one gene does not influence the allele received for another gene. Not only can genes on different chromosomes be independently sorted into gametes but also genes on the same arm of a chromosome can assort independently through the process of recombination. Recombination during meiosis via chromosomal crossing over differs from site-specific recombination, which can alter gene order and/or add new information to the genome (Alberts et al. 2002).

An important exception to the law of independent assortment occurs when the loci for two genes are too close together for recombination to occur frequently. Alleles at these loci appear together more often than expected by chance, causing linkage disequilibrium. Phenotypic traits at these physically close loci are considered to be linked.

## Mapping Gene Loci

The frequency of recombination for two loci is dependent on the physical distance between them. Loci that are closer together have a lower frequency of observed recombination, while loci

that are more distant have higher rates of recombination. Loci that are very distant may recombine at the frequency expected by chance.

The differences in frequencies of recombination can be used to determine the sequence of genes and their relative distances from each other (Becker et al. 2003). This distance is expressed in map unit or centiMorgans, where one centiMorgan corresponds to a 1% recombination frequency. One centiMorgan is roughly equivalent to one megabase of sequence on the physical map of the genome (Jobling et al. 2004).

More recent advances in genetics allow us to use quantitative trait loci (QTLs), loci that influence a quantitative phenotype of interest and contribute to a complex trait, to map gene locations. QTL mapping identifies associations between phenotypes and genotypes on a genome-wide scale, giving information not only about the genomic location but also the number and effect sizes of the loci that influence a phenotype.

## Nomenclature

Loci are expressed as *4q21.3*, where *4* is the chromosome number, *q* is the chromosome arm (*p* for the short arm, *q* for the long arm), *2* is the region, *1* is the band, and *3* is the sub-band. Bands are counted out of the centromere (center) of the chromosome to the telomere (end) after the chromosome has been stained with Giesma stain (also known as G-banding).

of obtaining the test data if the two gene loci in a chromosome are indeed linked to the likelihood of observing the same data purely by chance. If the LOD score is positive (high LOD score), it means that the gene loci are closely linked and therefore usually inherited together. If the LOD score is negative (low LOD score), it means a low linkage. LOD stands for “logarithm (base 10) of odds,” means that the number is expressed logarithmically.

## LOD Score

Log of odds; Logarithm (base 10) of odds

## Definition

A statistical test used for linkage analysis in human, animal, and plant populations.

## Introduction

The search for a method to detect linkage of major loci took 25 years, beginning with Bernstein (1931) and ending with LOD scores. In 1955, Newton Morton developed a statistical test (named LOD score) for linkage analysis (Morton 1955). When two gene loci are located on the same chromosome, the chance of a cross-over producing recombination between the gene loci is related to the distance between the two gene loci. Therefore, recombination frequencies have been used to develop linkage maps or genetic maps. In genetics, the LOD score has been applied to test whether two gene loci are likely to be located near each other on a chromosome and are therefore likely to be linked. The LOD score compares the probability/likelihood

## How to Calculate LOD Score

The calculation of a LOD score needs a large data of samples, which tend to yield more statistically meaningful information, because a large number of samples reduce the risk of flukes and clusters which twist the data (Morton 1996).

The LOD score is calculated as follows:

LOD score =  $\log_{10}(\text{probability of birth sequence with a given linkage value} / \text{probability of birth sequence with no linkage})$

To calculate the LOD score, a pedigree for two gene loci of interest should be established first. That is to say, the genotypes of parents and offspring are needed. Second, the number of recombinants and number of nonrecombinants are determined according to the genotypes of parents and offspring observed.

The third step is to calculate the probability of obtaining the results assuming the two loci are linked. This is given by

$$P_{\text{linked}} = \left( \frac{R}{R + NR} \right)^R * \left( 1 - \frac{R}{R + NR} \right)^{NR},$$

where R = number of recombinants and NR = number of nonrecombinants.

The fourth step is to calculate the probability of obtaining the results assuming the two loci are not linked. This is given by  $P_{\text{non-linked}} = \left( \frac{1}{2} \right)^{NR+R}$ , where R = number of recombinants and NR = number of nonrecombinants.

The fifth step is to divide the probability of obtaining the results assuming the two loci are linked by the probability of obtaining the results assuming the two loci are not linked. This is given by  $\frac{P_{\text{linked}}}{P_{\text{non-linked}}}$ .

At last, take the base 10 logarithm of the ratio obtained above. This is given by  $LOD \text{ score} = \log_{10} \frac{P_{\text{linked}}}{P_{\text{non-linked}}}$ .

A lower LOD score (negative) indicates less likelihood of genetic linkage (Nyholt 2000). A LOD score of 3 or higher generally means that two genetic loci are located close to each other on the chromosome, indicating 1000 to 1 odds that the linkage being observed did not occur by chance. A LOD score of 3 translates to a  $p$ -value of approximately  $0.05^3$  (Risch 1991).

## Conclusion

Recombination frequency, a measure of genetic linkage, is the frequency with which a single chromosomal crossover will take place between two genes during meiosis. LOD scores provide a method to unify linkage tests based on identity by pedigree and identity in marker state while permitting selection of the most informative individuals through their phenotypes and genetic markers in relatives. The LOD score is determined by taking the base 10 logarithm of the ratio of the linkage likelihood to the likelihood of no linkage. LOD score is a simple method to analyze complex family pedigrees in order to determine the linkage between two genetic markers.

## Long-Term Memory

Jason N. Bruck

Department of Integrative Biology, Oklahoma State University, Stillwater, OK, USA

### Synonyms

Autobiographical memory and procedural memory; Declarative memory; Episodic memory; Explicit memory; Semantic memory

### Definition of Long-Term Memory

Long-term memory is, conceptually, the process by which events, skills, procedures, and concepts are stored indefinitely in the mind. That is not to say that forgetting is impossible, just that there is no precisely defined point when that will happen (Greene 1987). The model most people are familiar with involves the movement of concepts from short-term or working memory into long-term memory with rehearsal or practice (Atkinson and Shiffrin 1968). It is thought that information moving through short-term memory is encoded into long-term memory through a process called synaptic consolidation which leads to the formation of a permanent change in the brain defined as an engram (Dudai 2004; Liu et al. 2012). This change in brain connections is thought to materialize physically as increased synaptic strength (increased dendritic formation) that is the result of cellular consolidation; however, recent research has illuminated this further, as it seems a specific pattern of connectivity of engram cells may be the crucial element for long-term storage (Ryan et al. 2015). Sleep is also considered to be an

important process for memory consolidation (see day night cycles in this volume; Ruch et al. 2012).

### What Is Remembered?

Long-term memories can be subdivided into explicit and implicit categories. Explicit memories are those that we have conscious reflections of and are further subdivided as semantic, autobiographical, and episodic memory. Semantic memory involves the facts one knows. When you are remembering information for a test or the meaning of words, that is semantic memory (Wood et al. 2012). Autobiographical memory involves the knowledge one has of the personal events that have impacted his or her own life (Conway and Pleydell-Pearce 2000). It contrasts with episodic memory in that autobiographical memory can only apply to personal events, whereas episodic memory can apply to events that have involved others and is more altered by the ravages of time and age than the other two subdivisions of explicit memory (Spaniol et al. 2006). Implicit memory, by contrast, deals with the mechanics of the body. This is where one's procedural ability to ride a bike or drive a car is centered (Foerde and Poldrack 2009). Considered a subconscious memory system, implicit memory is considered non-associative (Eysenck 2012). As we get better with these types of tasks, like writing or mechanical activities we are "primed," our performance is accompanied with greater speed and dexterity.

### What Is Forgotten?

Many neurodegenerative diseases, like Parkinson's disease, Alzheimer's disease, dementia, multiple sclerosis, Huntington's disease, and schizophrenia, are related to forgetting things. It is the associated damage to neuronal tissue that causes the lapses rather than normal forgetting processes. Even menopause in women can be associated with memory loss (Drogos et al. 2013). According to some, it is the process of sleep that helps us prune our

memories (Poe 2017). In normal functioning, forgetting is as important as remembering, and understanding what we remember and what we forget helps determine what things are ecologically relevant to both people and animals alike.

### **Long-Term Social Memory: An Evolutionary and Ecologically Relevant Test of Comparative Cognition**

In 1976, Nicholas Humphrey published a seminal paper on the “social function of intellect.” He argued that the problems faced by primates related to food acquisition or general survival could not explain the evolution of intelligence differences between species facing similar ecological pressures (Humphrey 1976). Humphrey argued that sociality accounted for the observed aptitude differences. It was the processing of social information, like recognizing and remembering individuals as well as tracking relationships of both self and others as well as between others, which proved to be the most relevant tasks of learning and memory faced by primates. Humphrey argued that the ability to perform match-to-sample tasks, sustain long-term memories for decades, or even engage in abstract problem-solving stems from the social demands that lead to complex behaviors such as tactical deception and tactical coalition formation (Dunbar 1998; also see Emery et al. 2007; Humphrey 1976).

To associate cognition with sociality, one needs a cognitive task that can be tested across species as an indicator of relevant cognitive evolution driven by the needs presented by a complex social system (such as fission fusion, see Aureli et al. 2008). Associating memory (or demonstrating recall, as a behaviorist might point out) with social recognition provides just such a task, because it leads naturally to the prediction that as social systems get more and more complex, the duration of conspecific memory retention should increase. This is a direct, semi-easily quantifiable cognitive measurement (not something as intractable and loaded as deceit or theory of mind), applicable to all species that have social recognition capabilities, and relates directly to the main ecological problem of a complex social

system: needing to remember more individuals for longer periods of time (Bruck 2013b).

Long-term social recognition is potentially necessary in the few species that exhibit fission-fusion dynamics where changes in the social group size and composition occur regularly (Connor et al. 2000; Isbell and Van Vuren 1996). Availability of food often causes dolphin pods to break up and reform, leading to separations that could last hours, days, or possibly even years (Connor et al. 2000; Connor and Whitehead 2005). Using signature whistles, dolphins advertise their individual identity and location to pod-mates after such separations (Caldwell and Caldwell 1965; Caldwell et al. 1990; Harley 2008; Janik 2009; Sayigh et al. 1998). In terms of nonkin long-term social recognition in nonhuman animals, dolphins have been systematically shown, so far, to have the longest social memory retention of more than 20 years (Bruck 2013a). Anecdotally, later tests performed on a 47-year-old dolphin using a signature whistle playback of a social partner she had not seen in 42 years indicated that dolphin social memory most likely rivals our own limits of approximately 50 years (Bruck, unpublished data; Bahrack et al. 1975). Individual-level recognition systems are found outside of cetaceans as well, and in many cases, we not only know that nonhuman animals can recognize individuals but also how long these social memories persist. For example, elephants are able to distinguish between the acoustic signals of over 100 different individuals from distances extending 1–1.5 km and can potentially remember olfactory cues of individuals for a decade or more (Hart et al. 2008; McComb et al. 2000, 2003; Rasmussen 1995; Rasmussen and Krishnamurthy 2000). In fur seals, mothers and pups are often separated as the mother hunts for food. When the mother returns, she uses her offspring’s call to reunite with the correct fur seal pup. Over time, however, this call changes as the pup grows. The mother not only remembers the specific call of her pup at the time; she also maintains long-term memories for the various different versions of her offspring’s call (Charrier et al. 2003; Insley 2000). As mentioned previously, humans maintain face memory for almost 50 years, even of unrelated individuals (Bahrack et al. 1975; Dasser 1985). For other fission-fusion species most likely to

<sup>a</sup>Denotes anecdotal observations, low sample size, and/or non-peer-reviewed publication

have persistent social memories, systematic studies have been conducted on corvids (3 years of long-term social recognition, Boeckle and Bugnyar 2012; Marzluff et al. 2010) and Japanese monkeys (3 years, Murai et al. 2011), and there is anecdotal information for hyenas (1 year, Holekamp et al. 2007) and elephants (2–27 years, sons to mothers, Rasmussen 1995), but there is little information for most nonhuman apes and parrots (see Table 1).

Long-term social recognition bridges the studies of cognitive science, comparative psychology, and evolutionary biology in an ecologically meaningful way. It is not possible to rank animal intelligence, despite the public pressure to do so. Comparative tests across taxa on ecologically

relevant cognitive tasks allow us, however, to make informed predictions about how evolution shapes animal minds. This is important, because it allows us to consider evolution in the study of animal minds.

## Synonyms

Long-lasting strengthening; Long-time acquaintance

## Definition

The continuous increase in conductivity and efficacy of synaptic transmission induced by

appropriate activation of the same synapses to carry out the action

## Introduction

The formation of declarative memory (e.g., memory required to remember the content for the next day exam) involves the activation and collaborative working of the neocortex, medial temporal lobe, and hippocampus. Memory formation requires the strengthening of synapses and is studied by *Hebb's rule* (Hudspeth et al. 2013). It is believed that synaptic potentiation is an efficient pathway for learning and formation of memories by the release of neurotransmitters. This activity leads to flexibility of synapses (Marieb and Hoehn 2007), and such plasticity is called Hebbian plasticity.

Hebb postulated: "When the pre-synaptic axon of Cell 1 is in close association with postsynaptic dendrite/cell body/axon of Cell 2, it continuously fires in order to elicit the response. Some growth or metabolic alterations take place in both Cell 1 and 2 to generate the action potential. In order for a stronger response and strengthened synapses, it is mandatory for both pre and post parts of the synapse to be active at the same time" (Squire et al. 2012).

An important phenomenon is seen during the formation of declarative memory in the hippocampus. Timothy Bliss and Terje Lømo in 1973 at Norway discovered high-frequency electrical stimulation (HFS) of an excitatory pathway to the hippocampus. It produced a long-lasting enhancement in the strength of the stimulated synapses in anesthetized rabbit (Squire et al. 2012). Such an effect or the synaptic phenomenon is termed as long-term potentiation (LTP) (Bear et al. 2007; Squire et al. 2012; Tortora and Derrickson 2008). It is the long-last strengthening of postsynaptic nerve cell for stimulation across the synapse. It occurs with repeated stimulation (Bear et al. 2007). However, it is only possible to potentiate the depolarized synapses and not the polarized ones.

Other than hippocampus, LTP has been observed in other brain regions such as cerebellum, neocortex, subcortical regions like amygdala, etc. (Hudspeth et al. 2013). In addition to mam-

mals, LTP is observed in other classes such as in neuromuscular junction of an arthropod, sensorimotor synapse of *Aplysia*, etc. (Squire et al. 2012). Interestingly, there is no such single method to induce LTP in all cases, but there are multiple mechanisms known that depend on the type of synapse and neuroanatomical position (Squire et al. 2012).

## Neuroanatomy of Hippocampus

Hippocampus is a folded structure of archicortex constituting dentate gyrus and areas of CA1 and CA3 (CA stands for *cornu ammonis*), which are two thin neuronal layers folded onto each other along with subiculum – a transitional cortex. The information gets relayed from one part of hippocampus to the other regions via various pathways that are made up of different fibers. Hippocampus receives its one of the major inputs from six-layered neocortex known as entorhinal cortex via perforant pathway. This pathway is an axon bundle directly stimulating the glutamatergic synapses of granular cells of dentate gyrus (Brady 2011; Hudspeth et al. 2013). It is called perforant because it perforates the dentate gyrus after traversing the hippocampal fissure. From dentate gyrus, the mossy fibers carry the information to the CA3 region forming again the excitatory glutamatergic synapses, and from here the branching occurs in various directions (Fig. 1):

- (a) Commissural fibers from CA3 region pass to the other side of hippocampus.
- (b) Efferents from hippocampus relay information to the hypothalamus or thalamus via fornix.
- (c) Recurrent collaterals form the association between the same and neighboring cells of CA3 region. They are the backward connections.
- (d) Schaffer collaterals pass on the information from CA3 to pyramidal cells of CA1 region.
- (e) The fimbria carries the information to the septum.
- (f) CA1 then sends its axons further to the subiculum and entorhinal cortex (Bear et al. 2007; Squire et al. 2012).

**Long-Term Potentiation,****Fig. 1** Microcircuits

within the hippocampus:  
The flow of direct information starts from the entorhinal cortex to dentate gyrus (granule cells) through perforant pathway. From here it gets relayed through mossy fiber axons to the pyramidal neurons of CA3 region. The information then gets transferred with the help of Schaffer collaterals to the pyramidal neurons of CA1 region. CA1 neurons also receive the input from contralateral hippocampus through commissural collaterals. The message is further carried by CA1 axons to the subiculum

Additionally, there is a direct pathway for the connectivity of many of these regions. It starts from layer III neurons of the entorhinal cortex and terminates into the glutamatergic synapses of CA1 (Brady 2011).

Second, LTP is long-lived. If it is induced in CA1 region in an awake animal, it can last for weeks to months to years and possibly for a lifetime (Bear et al. 2007).

Apart from these LTP has three other properties:

**Properties of LTP in CA3-CA1 Region**

Hippocampal LTP is input specific, i.e., process and conduction of LTP is only seen when the neurons are stimulated with appropriate input. The effectiveness of synapse conductivity is seen once the presynaptic neurons are externally stimulated by an electrical stimulus. Apart from generating LTP through tetanizing, it can also be generated by antagonizing the actions of inhibitory neurotransmitters like GABA, serotonin, etc. (Kandel et al. 2014).

Main function of LTP is to keep the synapse active for a longer period of time when the presynaptic neuron is releasing neurotransmitters and postsynaptic neuron is highly depolarized. This type of synaptic plasticity has two remarkable features. First, it can be induced by brief exposure of tetanus for even less than a second. It will produce frequencies within a normal range.

1. Input specificity: EPSP is not generated when an untetanized low-frequency stimulus is delivered. The only synapse triggered with tetanus shows the properties of LTP.
2. Cooperativity: Strong stimulatory response is only possible when many afferent fibers are elicited by the stimulus displaying spatial summation. It implies that the magnitude or change in the response is only generated when high- and low-frequency-stimulating afferents *cooperate* in order to generate LTP.
3. Associativity: This property is displayed by the synapse when a weak tetanic stimulus fails to elicit a response. The tetanic stimulus from the contralateral or ipsilateral side from other pathways pairs up with a weak response and tends to elicit the response of LTP (Bear et al. 2007).

These Hebbian properties are not universal form of LTP and are not displayed by the mossy

fibers of CA3 synapse or by the Purkinje cell synapse in the cerebellum (Bear et al. 2007). They are unique to the CA1 region.

### Mechanism of LTP in CA1 Region

The amino acid glutamate is responsible for the excitatory synaptic transmission in hippocampal region. Glutamate receptors are of two types: AMPA ( $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor or AMPAR) and NMDA (N-methyl-D-aspartate receptor or NMDAR) receptor subclasses. The process of LTP follows the following processes. It begins by passing of  $\text{Na}^+$  (sodium) ions through the AMPA receptors in order to generate EPSP at the synapse of pyramidal cells (Bear et al. 2007). NMDA receptors are present on the postsynaptic part. They are of two types: (a) voltage-gated and (b) ligand-gated ion channels. They are in the blocked condition and don't permit the passage of  $\text{Ca}^{2+}$  (calcium) ions (Marieb and Hoehn 2007).

Soon after the transmission of  $\text{Na}^+$  ions and binding of glutamate that is released from the synaptic vesicles of the presynaptic region, their sole purpose is to conduct the  $\text{Ca}^{2+}$  (calcium) ions (Hudspeth et al. 2013) (Fig. 2).

Accumulation of these  $\text{Ca}^{2+}$  ions results in activation of two types of protein kinases: (a) protein kinase C and (b) calcium-calmodulin-dependent protein kinase II (CaMKII) (Hudspeth et al. 2013). Their activation sends signal to the nucleus that huge amounts of proteins are required by a molecular messenger called CREB (cAMP response element-binding protein). The BDNF (brain-derived neurotrophic factor) helps in the formation of these proteins (Marieb and Hoehn 2007). These two protein kinases are known to cause an increase in the ionic conduction of the channel via two pathways: (a) by phosphorylation of existing AMPA receptors (GluR1 subunits) and (b) by inserting entirely new AMPA receptors into the postsynaptic membrane leading to its "AMPAfication" (Hudspeth et al. 2013; Morris 2003). Soon after the release of  $\text{Ca}^{2+}$  ions and protein kinases, NMDA receptors help the

**Long-Term Potentiation, Fig. 2** Simultaneous activity of pre- and postsynaptic neurons leads to activation of NMDA receptors. (a) Activity at postsynaptic membrane during resting potential: Glutamate neurotransmitter binds to AMPA and NMDA receptors allowing the entry of sodium ions. This results in depolarization of polarized

membrane, which then displaces magnesium ions from NMDA channel. (b) Activity at postsynaptic membrane during depolarized (action) potential: Soon after the displacement of magnesium ions, calcium enters through NMDA channels and activates secondary messenger pathways. (Adapted from Bear et al. 2007; pp. 718)

membrane to depolarize and displace  $Mg^{2+}$  ions that were clog the ion channels (voltage-dependent blockade) (Bear et al. 2007). NMDA receptors are also known as Hebbian detectors as they provide correct measure of activation of pre- and postsynaptic parts simultaneously (Hudspeth et al. 2013).

The  $Ca^{2+}$  influx is possible via two ways:

- The inflow of calcium ions through ionotropic GluRs, especially N-methyl-D-aspartate receptor (NMDAR).
- The  $Ca^{2+}$  rush through voltage-gated calcium channels (VGCCs) (Squire et al. 2012).

## Maintenance of LTP

For LTP to take place for a long period of time, it is very important for the synapse to remain active for prolonged periods. There are two documented processes that bring such alterations:

- (a) There are four subunits that make up CaMKII. Activation of  $Ca^{2+}$  leads to their phosphorylation, and even after the return of  $Ca^{2+}$  ions to their resting phase, these subunits remain phosphorylated. This is helpful in reviving the subunit which gets dephosphorylated. The neighboring subunits come and activate it again thus keeping the LTP live for long duration (Bear et al. 2007).
- (b)  $Ca^{2+}$  ions also stimulate an isoform of adenylyl cyclase for increasing the concentration of AMP (adenosine monophosphate) available for LTP (Hudspeth et al. 2013; Kandel et al. 2014).

A retrograde messenger is also needed to travel in backward direction and enhance the glutamate release. This is performed by NMDA  $Ca^{2+}$  ions that signal and generate one such molecule – nitric oxide (NO). This molecule is synthesized by nitric oxide synthase (NOS). NO diffuses through the synaptic cleft into the presynaptic membrane and stimulates the guanylyl cyclase for the release of glutamate (Hudspeth et al. 2013). Endocannabinoids are also a type of retrograde messengers (Marié and Höhn 2007).

Importance of these  $Ca^{2+}$  ions and its proteins can be evaluated after inhibiting the accumulation of  $Ca^{2+}$  ions or any of the two kinases. Inactivating them or blocking their path doesn't permit the formation of LTP (Morris 2003).

## Can LTP Be Termed as Memory Formation?

There are ongoing discussions, and experiments are being carried out to ascertain whether LTP coincides with learning and memory formation. Experiments in a gene knockout mice suggested that LTP is severely impaired at the synapses present in the pathway of entorhinal cortex to dentate gyrus. But the spatial memories that tend to include this particular region for its formation show no signs of disturbance. This proves that there is no relativity between LTP and spatial navigational memory. Alternatively, it can be said that LTP doesn't take the charge of formation of such type of memory (Hudspeth et al. 2013).

It is also suggested that LTP contributes to the formation of declarative memories. The evidence to this statement comes from the fact that the same molecules that are involved in the mechanism of LTP are also responsible for learning and memory formation of declarative memories. Both of these processes have a common requirement of the activation of NMDA receptors after the AMPA receptors.

## Louis Leakey

Penthai Siriwat<sup>1</sup> and Sonia Tiedt<sup>2</sup>

<sup>1</sup>Oxford Brookes University, Oxford, UK

<sup>2</sup>Imperial College London, School of Public Health and Grantham Institute, London, UK

Louis Leakey (b. 1903–d. 1972) was a prominent paleoanthropologist who paved the way in the field of primate and human evolution in Africa.

## Personal Life

Louis Seymour Bazett Leakey was born on August 7, 1903, in Kabete, Kenya. His parents, Harry and Mary Leakey, were English missionaries to the Kikuyu tribe. In 1921, Leakey traveled back to England and matriculated at Weymouth and St. John's College, Cambridge University, reading in anthropology and archaeology. In 1930, Leakey received his doctorate in African prehistory based on findings near Lake Elmenteita in northwest Kenya.

In his personal life, Leakey married his first wife, Frida Avern, in 1928 and had a son Colin Leakey. They divorced in 1936, and Leakey later remarried that year to fellow archaeologist and illustrator, Mary Nicol. They moved to Kenya and had three sons, Jonathon (1940), Richard (1944), and Philip (1948).

## Works

After he completed his studies in 1924, Leakey traveled back to East Africa to begin his archaeological expedition. Leakey strongly believed that humans originated from Africa and that East African fossils were far older than was previously believed (Isaac and McCown 1976). At the time, this idea was incredibly controversial as species origins were believed to be from Asia or Europe. Leakey's excavation in 1931 at the Olduvai Gorge in Tanzania marked his first and most prominent excavation which shifted the theory of evolution

to be centered in Africa. There, Leakey uncovered animal fossils and ancient stone tools, which were called Oldowan tools. However, it took some time until 1969 before the site developed into a major excavation site.

In 1948, Mary Leakey and the Leakey team made a significant discovery of the complete fossil remains of *Proconsul africanus* on Rusinga Island. This fossil was found to be an ancestor of apes and humans over 18 million years ago (Leakey 1948). Furthermore, in 1962 in east Lake Victoria in Fort Ternan, Leakey's team discovered the remains of *Kenyapithecus*, which provided another link between apes and early man dated 14 million years ago (Leakey 1961). One of the most prominent findings at the Olduvai Gorge excavation site occurred in 1959 by Mary Leakey, who discovered the renowned fossil *Australopithecus* (*Zinjanthropus*) *bosei*. This hominin fossil was nicknamed the "Nutcracker Man" as its jaw was evolved for heavy repetitive chewing (Leakey 1959). The cranium fossil was dated 1.8 million years old.

In 1959, the Leakey excavation team which now included Mary and Leakey's first son, Jonathan, discovered a fossil of a juvenile hominid. The lower jaw and partial top of the skull piece belonged to *Homo habilis* or the handyman. The partial skeleton, dubbed "Johnny's Child," was dated 1.8 million years old and speculated to have created Oldowan stone tools which were found nearby. These findings led Leakey to theorize that the *H. habilis* and *Z. bosei* fossils originated from coexisting, but separate hominid lineages. In fact, Leakey and two other paleoanthropologists, Philip Tobias and John Napier, proposed that *Z. bosei* was not a direct ancestor of modern man due to differences when compared to *H. habilis* (Leakey et al. 1964). This new proposition suggested that the Olduvai fossils met a defining criterion for "homo," which included an upright posture, bipedal gait, and dexterity to stone tools. Furthermore, it was proposed that *H. habilis* was an advanced hominin which lived contemporaneously with *Z. bosei* in east Africa and represented an evolutionary step between *Australopithecus* and *H. erectus* (ancestor of *H. sapiens*) (Leakey et al. 1964). Although the

significance of the findings were widely accepted, the proposed theory faced with skepticism since its proposal in the 1960s until this day as an ongoing debate about the origins of modern humans.

Mary and Leakey were among the pioneers in their field in using newly developed tools and techniques such as isotopic dating in researching Stone Age artifacts (Leakey 1971). Analysis of Oldowan artifacts showed that it was significantly older than any known stone tool technology in Europe. This backed the idea that human predecessors originated in Africa, rather than Europe or Asia.

## Other Works

Throughout his career, Leakey's numerous various books include *The Stone Age Cultures of Kenya Colony* (1931), *Adam's Ancestors* (1934, rev. ed., 1953), *White African: An Early Autobiography* (1937), *Stone Age Africa* (1936), *White African* (1937), *Olduvai Gorge* (1951), *Mau Mau and the Kikuyu* (1952), *Olduvai Gorge, 1951–1961* (1965), *Unveiling Man's Origins* (1969, with Vanne Morris Goodall), and *Animals of East Africa* (1969).

Later in his career, Leakey focused on his academic path where he held appointments at British and American universities while also fundraising for projects. Mary Nicol and their second son, Richard, continued excavations in Africa. From 1945 to 1961, he was appointed as a curator of the Coryndon Memorial Museum in Nairobi. In 1961, he established and became the director of the Centre of Prehistory and Paleontology. In 1958, Leakey founded the National Primates Research Center with Cynthia Booth (previously known as Tigon Primate Research Centre) which became a main center for primate research.

Leakey believed that our understanding of human evolution can be enhanced through our understanding of behaviors of early ape-like ancestors. He was instrumental in support prominent mentees which include Jane Goodall and her research of chimpanzees in Gombe, Dian Fossey and her studies of mountain gorillas in Rwanda,

and Biruté Galdikas insights of orangutans in Borneo. The research of apes in the wild was formative and revolutionary in the course of primate research.

## Legacy

Leakey passed away on October 1, 1972, in London, England. The work led by Leakey and his team was groundbreaking and formed the vital understanding of the earliest origins of human life. The contribution of the Leakey family to natural sciences in the fields of primatology, paleoanthropology, and wildlife conservation continues to this day. In 1968, the Leakey Foundation was established to ensure the legacy of the Leakey family work in the study of human origin. The International Louis Leakey Memorial Institute for African Prehistory located in Nairobi, Kenya, remains a fossil repository, which includes laboratory and research facilities, and stands today as a testament to Leakey's accomplishments.

## Louis M. Herman

Adam A. Pack

Departments of Psychology and Biology,  
University of Hawaii at Hilo, Hilo, HI, USA  
The Dolphin Institute, Hilo, HI, USA

## Introduction

The renaissance period of animal cognition in the early 1970s (Hulse et al. 1978) witnessed the emergence of several notable figures that championed an effort to describe the cognitive characteristics (i. e., abilities, specializations and limitations) of different species. Louis M. Herman was among these pioneers whose findings ushered in a new view of animal cognition that extended beyond the restrictive stimulus-response lens of the past. Considered by many to be the “father” of dolphin cognition, Dr. Herman spent nearly 50 years with his many students and colleagues conducting groundbreaking studies that revealed the remarkable cognitive capacity of bottlenose dolphins (*Tursiops truncatus*). In parallel with these efforts, he pioneered the scientific study of humpback whales (*Megaptera novaeangliae*) in Hawaiian waters. The marine mammal laboratory Dr. Herman created became world renowned not only for its scientific studies and breakthroughs in the study of dolphin cognition and whale behavior but also for the unique applied learning opportunities it provided to students of all ages through volunteer apprenticeship programs, college-level internships, and higher level degree programs. On August 3, 2016, after five decades of research and publishing about dolphins and whales, Dr. Herman passed away. Full biographies of Dr. Herman's life and remarkable career in marine mammal science can be found in Herman (2012) and Pack et al. (2017).

## Background, Education, and Early Career Directions

Louis M. Herman was born in Queens, New York, in 1930. He earned his bachelor's and master's

degrees in Psychology at City College of New York. After serving as an intelligence officer in the US Air Force and studying concept learning in rhesus monkeys at Emory University in Atlanta, Georgia, Dr. Herman entered the doctoral program at Pennsylvania State University where he investigated human information processing. His dissertation, awarded in 1961, explored how humans process information when confronted with competing cognitive demands from two simultaneous auditory tasks. The American Institutes for Research honored Dr. Herman's work with first prize in their inaugural "Creative Talent Award" in Psychology. In their citation of Dr. Herman's work, eminent psychologists Harry Harlow, James Miller, and Theodore Newcomb wrote "This thesis, beautifully conceived and executed, displays a wealth of knowledge and historical documentation on a modern problem of great significance in psychology" (Harlow et al. 1962, p. 681). Dr. Herman continued his studies of human information processing and performance at North American Aviation in Columbus, Ohio, from 1961 to 1963 and at Queens College in New York City as an assistant professor from 1963 to 1966 (see Pack et al. 2017 for references to some of these studies). In 1966, he joined the Psychology Department at the University of Hawaii at Manoa where he remained for the rest of his career. In his personal life, he was an avid long distance ocean swimmer and most importantly a devoted husband and father to his wife Hannah and their daughter Elia.

### **Founding the First Laboratory Fully Devoted to Dolphin Cognition**

When he joined the University of Hawaii, Dr. Herman's research plans were to continue his studies with humans; however, his attention was soon diverted to another large-brained social mammal, the bottlenose dolphin, whose cognitive capacities he realized had received surprisingly little scientific investigation (see Herman 2012 for examples of some early work). An intriguing summer study on dolphin rule learning at Hawaii's Sea Life Park in 1967 serendipitously

turned into an opportunity to have dolphin pupils at a laboratory of his own creation that could be fully devoted to the study of dolphin sensory perception, cognition, and language comprehension. In 1969, after locating and converting an abandoned shark display facility to house dolphins, Dr. Herman launched the Kewalo Basin Marine Mammal Laboratory (KBMML). There, together with his dolphin pupils (Keakiko, Nana, Puka, Akeakamai, Phoenix, Hiapo, and Elele), 38 graduate students, and scores of undergraduates, he produced numerous groundbreaking studies in dolphin cognition and humpback whale behavior. Following the close of KBMML in 2004, Dr. Herman continued his innovative studies of humpback whale behavior until his passing (summarized in Herman 2016).

### **Dolphin Sensory Perception and Cross-Modal Abilities**

Recognizing that little was known about dolphin sensory perception, Dr. Herman's earliest studies at KBMML explored dolphin hearing and vision as a foundation for future inquiries into dolphin cognition. Starting with dolphin hearing, Dr. Herman demonstrated the dolphin's ability to detect small degrees of frequency modulation and its sensitivity to other types of sounds as well as temporal differences in sounds (summarized in Herman 1980b). Dr. Herman next tackled dolphin vision, performing pioneering studies of dolphin visual acuity that showed that dolphins see well (about 8–12 min of arc) both in air and underwater (Herman et al. 1975). He also explored the dolphin's sensitivity in different areas of the visible spectrum and characterized its limitations in discriminating different colors (Madsen and Herman 1980). Much later, Dr. Herman and his students revealed that dolphins could immediately recognize complexly shaped objects across echolocation and vision (Herman et al. 1998; see also summary in Pack et al. 2004). For the latter work, Dr. Herman and his coauthors received the American Psychological Association Division 6's F.A. Beach Comparative Psychology Award for best paper published in the *Journal of Comparative Psychology* in 1998.

## Dolphin Rule Learning and Concept Formation

In the 1970s, Dr. Herman began investigating the efficiency with which dolphins could acquire and apply generalized rules and concepts, in keeping with other animal cognition studies of the times. His work with learning sets showed that dolphins could learn and apply a “win-stay, lose-shift” rule across numerous novel problems after a single trial with arbitrary sounds and also that they could immediately shift response strategies within problems after reward contingencies were reversed. They performed both of these tasks at levels comparable to what had been shown with nonhuman primates (Herman 1980b). Dr. Herman and his students also investigated the dolphin’s ability to develop a concept of same/different and apply this to novel problems in different modalities. Using matching-to-sample (MTS) tasks as well as tasks involving symbolic judgments of similarity and difference using either simultaneously presented stimuli or successively presented stimuli, the dolphins performed accurately on first trials across numerous problems with novel auditory and visual materials (Herman 1980b; Herman et al. 1993b; Mercado et al. 2000). With one dolphin, acquisition of the same/different concept was near instantaneous suggesting that when confronted with tasks requiring judgments of similarity and difference, dolphins, like chimpanzees, may be predisposed toward cognitive solutions involving concepts rather than memorizing stimulus-specific rote associations (Herman et al. 1993b). Finally, in the mid-1990s, Dr. Herman and his students began to investigate the types of mental representations of objects dolphins formed through echolocation. The results of these studies revealed that complexly shaped objects inspected by the dolphin through echolocation were represented holistically rather than through individual features. They also showed that objects that had never previously been experienced simultaneously through echolocation and vision, as well as novel objects, could be matched across these senses (summarized in Pack et al. 2004). Collectively, these studies demonstrated that dolphins can abstract a same/different

concept from relatively few exemplars and can readily apply that concept on first trials across numerous pairs of novel stimuli in different modalities and even across the senses at levels comparable to those demonstrated with some non-human primates.

## Dolphin Memory Abilities and Processes

In the 1970s, recognizing that memory is the bedrock upon which all cognition rests, Dr. Herman and his students also investigated for the first time dolphin short-term memory abilities and processes. Early work is summarized in Herman (1980b). In studies of auditory MTS in which various delays were interposed between the offset of the sample sound and onset of the alternative sounds, Dr. Herman showed that matching accuracy remained at or near ceiling levels across hundreds of pairs of novel sounds for nearly all delays tested up to 120 sec (the longest delay tested), a finding comparable to what has been found in several species of nonhuman primates (Herman 1980b). He also showed that like visual short-term memory in primates, short-term memory for sounds in MTS tasks was subject to both proactive interference (i.e., interference from earlier experienced sounds on the memory of later sounds), as well as retroactive interference (i.e., interference from noise inserted during the delay period on the memory of sounds experienced prior to the delay). In some of the first serial-probe-recognition tasks run with animals, in which a list of sounds was followed by a probe sound which the dolphin judged symbolically as either on or absent from the list, Dr. Herman showed that memory span for lists of novel sounds was between four and five sounds. He also demonstrated a recency effect with increasing list length, as had been shown in humans and nonhuman primates. Later, Dr. Herman and his students extended these studies by demonstrating that short-term memory retention abilities for various types of visual materials were comparable to those witnessed with auditory materials and that the dolphin was also capable of maintaining representations of motor behaviors either performed by

another dolphin or behaviors that were self-performed (Herman et al. 1993b; Herman 2002). In a unique variant of the latter task, Dr. Herman and his students taught a dolphin to respond to a “repeat” command by repeating the last behavior it performed and also to an “any” command by performing any one of five behaviors except the one that it last performed. The dolphin was tested on different sequences of four commands. Each sequence began with a command to perform a specific behavior. The next three gestures were different combinations of “any” and “repeat.” The dolphin performed with high accuracy, including on those trials in which it was required to repeat self-selected behaviors (Herman 2002). The dolphin’s ability to correctly carry out these sequences demonstrated important aspects of the management of working memory including maintaining, monitoring, and updating mental representations. Collectively, these studies showed that dolphins have well-developed short-term memory capabilities and working memory processes that can flexibly handle material in different modalities and which are critical for supporting higher-level cognitive tasks.

### Dolphin Imitative Abilities

In many ways, Dr. Herman was ahead of his time in terms of recognizing the significance of particular aspects of animal cognition. For example, prior to a renewed interest in animal imitation and the recognition of its complexity and importance in social learning in the 1990s, Dr. Herman and his students had already conducted groundbreaking laboratory studies of imitation in dolphins, who in the wild demonstrate a natural ability to copy the signature whistles of close companions and closely coordinate similar behaviors with these individuals (Herman 2002). They showed for the first time that a dolphin could imitate with high fidelity a variety of arbitrary computer-generated familiar and novel sounds (Richards et al. 1984) and also that it could imitate a variety of familiar and novel arbitrary behaviors produced by either another dolphin or by a human (either in the dolphin’s habitat or at

tank-side or displayed on a small television monitor placed behind an underwater window) (Herman 2002). The ability of the dolphin to imitate both novel sounds and motor behaviors, and to respond to an “imitate” signal (in contrast to other signaled commands), demonstrated that it could develop a broad and generalized concept of imitation thus far unmatched in studies with other nonhuman animals.

### Studies of Dolphin Social Awareness and Self-Awareness

In the 1990s, Dr. Herman and his students began to investigate forms of social awareness beyond imitation. These studies focused on the management of joint attention between an informant and a receiver toward objects of interest by testing the dolphins’ understanding of human pointing and/or gazing. Joint attention is recognized as an essential component of social cognition (Pack and Herman 2006). Early work with nonhuman primates showed that they had difficulty in comprehending pointing cues, unless the tip of the informant’s pointing finger was positioned nearly touching a focal object (reviewed in Pack and Herman 2006). In contrast, Herman et al. (1999) demonstrated that dolphins could respond accurately on first trials to dynamic brief human pointing cues toward distal objects including those placed behind the dolphin. The dolphin could also immediately understand sequences of pointing cues when these were substituted for gestural references to objects that instructed the dolphin to create relationships between two objects (see section on sentence comprehension below). Later work extended these discoveries by demonstrating that dolphins could immediately understand static human pointing cues as well as both static and dynamic human gazing cues at objects (Pack and Herman 2006). Together, these studies showed that the dolphins understood the referring function of pointing and gazing, and they complemented other work performed at Epcot’s Living Seas facility in Florida by some of Dr. Herman’s former students and colleagues showing dolphins spontaneously producing

pointing behaviors (by aligning their rostrum and body toward an object) and understanding the importance of attentiveness of a receiver (reviewed in Pack and Herman 2006). Dr. Herman and his students also studied various forms of self-awareness. They showed that a dolphin could on command recall its own actions including those behaviors of its own choosing or creation (summarized in Herman 2002). They also showed that a dolphin could both understand human-directed references to its own body parts and could use referenced body parts in different ways (e.g., to touch or toss an object) (Herman et al. 2001). This work adds to the understanding of dolphin self-awareness, which has also been demonstrated in mirror self-recognition studies (Reiss and Marino 2001).

### Studies of the Interpretation of Television Displays

One of the most unexpected and remarkable abilities shown in dolphins by Dr. Herman was their capacity to spontaneously (i.e., without training) understand television displays as representations of the real world. When confronted for the first time with the small, 20 cm image of a trainer on a television monitor placed behind an underwater window in their habitat, both the dolphins Phoenix and Akeakamai (Ake) immediately understood gestural signs given by this trainer including, for Ake, imperative sentences within her language (see section below on sentence comprehension) (Herman et al. 1990). The immediacy with which the dolphins interpreted these television displays as representations of the real world stands in contrast to the initial difficulty common chimpanzees had with this understanding (Savage-Rumbaugh 1986). In addition to understanding the gestural signs from the small image of a trainer, the dolphins also understood gestural signs that were reduced to point-light displays (i.e., points of light against a black background moving about in place of the trainers arms and hands) (Herman et al. 1990). Further studies showed that they also understood the relationship between a small, televised image of an object and

the same real-sized object inspected through echolocation (Pack et al. 2004), and could imitate televised behaviors of a human (Herman et al. 1993b; Herman 2002).

### Studies of Comprehension of Sentences by Dolphins

Arguably, the most notable of Dr. Herman's contributions to the field of animal cognition have been in language comprehension (Herman 1986, 1987, Herman and Forestell 1985; Herman et al. 1984, 1993a,b). Dr. Herman created two artificial language systems in which either human-generated gestural signals (taught to Ake) or computer-generated acoustic signals (taught to Phoenix) were used to express individual "words" in various semantic categories (agents, objects, actions, modifiers, relationships). Sequences of words were used to compose sentences up to five words in length according to various syntactic frames and constraints. A "sentence" was defined as "a sequence of words that expressed a unique semantic proposition" (Herman et al. 1984, p. 135) and was given in the imperative or interrogative mode. Imperatives required the dolphin to take named actions to named objects taking into account their named modifiers or asked the dolphin to construct a relationship between two named objects. To illustrate the complexity of some of the imperatives, the five-word relational sentence *Right Hoop Left Ball Fetch* asked Ake to take the ball on her left to the hoop on her right, with pairs of hoops and balls present as well as other named objects. The modifiers *Left* and *Right* could exchange positions in the sentence as could the objects *Hoop* and *Ball*, and the relationship term *In/On* could be exchanged for the relationship term *Fetch* to create a variety of new instructions, all of which Ake understood. The findings (see earlier citations) established the ability of Phoenix and Ake to take account of both the semantic and syntactic features of their separate language systems to carry out the instructions embedded in the sentences. Among other things, the dolphins could understand instructions new to their experience, derive the meaning of new

syntactic frames that were extensions of existing frames, understand the different meanings of novel sentences in which the same words were placed in different orders, decode semantically or syntactically anomalous sentences, and immediately generalize the lexical references to objects to include different exemplars of those objects. The only other nonhuman species that has shown similar capabilities for comprehension of novel sentences using a variety of objects and in different contexts is the Bonobo (*Pan paniscus*) (Savage-Rumbaugh et al. 1993). In addition to understanding imperative sentences, Ake could report accurately (by responding on *yes* or *no* paddles) whether a named object was present in or absent from her habitat (interrogative sentences). For example, the interrogative *Frisbee Question* asked whether the named object *Frisbee* was present or not in the dolphin's habitat. The ability of the dolphin to report that a symbolically referenced object was absent from the habitat as well as to understand the same symbol in a variety of different sentence types and contexts was strong evidence that language symbols were understood referentially (Herman and Forestell 1985; Herman et al. 1993b).

### Field Studies of Humpback Whale Behavior

The multitude of diverse and innovative studies described above could alone characterize a remarkable career. However, as noted earlier, Dr. Herman was also prolific in the studies he and his students conducted on humpback whale behavior in their Hawaiian breeding grounds and Alaskan feeding grounds. In 1976, when most people were unaware of the presence of humpback whales in Hawaiian waters, Dr. Herman pioneered their scientific study with the first aerial and boat-based surveys of their numbers, association patterns, and habitat use (see Herman 2012). He then created one of the longest continuous field studies of the behavioral ecology of humpback whales ever conducted and through this was able to trace the life histories of individual whales for over 30 years (Herman et al. 2011). The work of Dr.

Herman and his students produced a wealth of new information on humpback whale behavior, which Dr. Herman summarized in his final publication on humpback whales produced in the last year of his life (Herman 2016). Some of these findings were the description of the behavioral role and coining of the term “escort” to describe the whale(s) accompanying a mother-calf pair; that males demonstrate mate guarding in the breeding grounds; that male-male competition over single females in the breeding grounds can escalate from dramatic displays to blood-shedding fights; that male size confers an advantage in competition; that affiliations between humpback whales in the breeding grounds (other than mother-calf pairs) are best characterized as transient; that playback of humpback whale song is much less attractive than playback of a feeding call in the breeding grounds (a finding that later served to help rescue “Humphrey the Wrong Way Whale” from San Francisco Bay in 1985); that males prefer to associate with females without calf (i.e., those with a higher reproductive potential), rather than females with calf (i.e., those with a lower reproductive potential); that across years, females vary their migratory timing depending on their reproductive status; that larger females produce larger calves and tend to attract greater numbers of male escorts than do smaller females; that mature females prefer associating with larger sized adult males; that females with calf tend to segregate into shallow water to avoid male harassment; that both mature and immature males sing in the breeding grounds; and that the mating system in humpback whales has the essential requisite characteristics of a lek mating system.

### Conclusions

Dr. Herman's collective works are documented in 181 scientific publications including two edited books (Herman 1980a; Roitblat et al. 1993). His discoveries have been featured nationally and internationally in over 230 newspaper and magazine articles, radio broadcasts, television documentaries, and IMAX films. At a point in history when much of animal cognition research was

focused on rats, pigeons, and nonhuman primates, Dr. Herman's findings compelled researchers to take notice of the similarities in cognition between dolphins and apes despite their divergent evolutionary lines. Dr. Herman's genius was also in his creative approach to designing scientifically rigorous and unique methods to ask each research question of *dolphins* (in contrast to humans or nonhuman primates) and to continuously adapt his approach in response to the dolphins' behaviors. From the outset, Dr. Herman's goal was to describe dolphin cognition within a comparative framework and "to understand eventually the pressures selecting for intellect and how particular cognitive specializations are adaptive" (Herman 1980b, p. 364). Dr. Herman continued working diligently to reach this goal until his passing. His revelations reinforced his earliest ideas that aside from the dolphin's relatively large brain size, a major evolutionary impetus for the development of its broad, flexible, and sophisticated suite of higher cognitive skills appears to be the elaborate social matrix and communication network typical of wild dolphin societies in which cooperation and competition play roles, the strengths of individual relationships are constantly being assessed, and young calves enjoy a protracted period of parental care through which to observe and learn (Herman 1980b, 2006). In 2004, Dr. Herman was honored as an American Psychological Association's President's Program Featured Speaker, and in 2008, his work with dolphins as well as humpback whales was recognized among the top 100 pioneering accomplishments in the history of the University of Hawaii. Beyond these and many other accolades, Dr. Herman will always be remembered as a pioneer who led one of the most productive long-term field studies of any whale species and advanced the field of dolphin cognition from virtual ignorance to a well-established position in the history of animal cognition research.

## Lucy

Wouter Schaake  
University of Utrecht (Alumnus),  
Utrecht, The Netherlands

## Synonyms

AL 288-1; *Australopithecus afarensis*  
(*A. afarensis*)

## Definition

A notable female specimen of an early hominid classified as *Australopithecus afarensis*. Upon discovery, Lucy's fossilized remains were coded as AL 288-1.

## Introduction

Lucy is the name given to a female specimen of *Australopithecus afarensis*, a relatively early variety of the hominid lineage that ultimately gave rise to the currently existing human species of *Homo sapiens* (modern humans). Lucy's fossilized remains were uncovered at a Pliocene (~5.3–2.6 MYA) site in Hadar, Ethiopia, in 1974. Other fossils of *Australopithecus afarensis* were also found in Laetolil, Tanzania, during the same period, resulting in the initial classification of the species, as well as its placement in the genus *Australopithecus* (from Latin: *southern ape*). The genus is defined by its combination of distinctively human and ape-like features, such as human-like skeletal features well adapted for bipedalism (walking on two legs), ape-like skeletal features adapted for life in the trees, and

relatively ape-like dental properties and brain size (Pontzer 2012). The specimens found at Hadar and Laetolil clearly belonged to the *Australopithecus* genus but differed significantly from previously known species, resulting in it being designated as the new species *A. afarensis* (Johanson et al. 1978).

## Bipedalism

One of the traits that made the discovery of “Lucy” and her conspecifics very interesting is the apparent adaptation for habitual bipedal locomotion (walking on two legs) that was exhibited by their remains. Even though *A. afarensis* seemed to have been able to walk on its hindlimbs, *A. afarensis* also retained elements of skeletal morphology in the forelimbs that are typical of knuckle walking such as seen in modern day African great apes (Richmond et al. 2001). The presence of adaptations suggesting divergent movement strategies makes it difficult to draw definite conclusions about locomotive habits of this early hominid. Still, examination of skeletal morphology suggests that *A. afarensis* was well adapted for bipedal locomotion. However, the hypothesized gait of this species shows relatively few similarities with that of modern humans. Instead, evidence suggests the species' strides were shorter and its walking velocity lower than that of modern humans, despite the relatively larger amount of energy used (Jungers 1982).

## Ecology

Despite the ostensibly more “primitive” walking gait of *A. afarensis*, evidence uncovered recently shows that the species showed adaptations considered to be more directly related to effective bipedalism. The morphology of a newly discovered fossilized metatarsal (middle foot) bone suggests that the foot of *A. afarensis* was nearly identical in function to that of modern humans, making it ideally suited for walking on the hindlimbs (Ward et al. 2011). This discovery

supported the hypothesis that *A. afarensis* was an obligatory terrestrial biped but is in itself not enough to rule out a partially arboreal ecology.

When looking at the morphology of the scapula in this species, it appears that *A. afarensis* was generally well adapted for climbing (Jungers 1982). A range of specimens of different ages shows that throughout development, *A. afarensis* retained scapular properties typical of suspensory primates, whereas these properties are lost during maturation in commonly ground-dwelling species (Green and Alemseged 2012). Evidence thus suggests that *A. afarensis*' behavioral repertoire consisted of a substantial amount of climbing (Green and Alemseged 2012; Stern and Susman 1983). Interestingly, sexual dimorphism in uncovered fossils shows that males were commonly larger and seemingly less well adapted to an arboreal lifestyle and thus likely engaged in terrestrial locomotion more often than females did (Jungers 1982). Ultimately, given that this hominid's anatomy appears well adapted for both arboreal and terrestrial lifestyles, *A. afarensis*' may have had the lifestyle and anatomy of a generalist ape (Stern and Susman 1983).

## Intelligence and Social Structure

Evidence regarding intelligence in early hominids often remains circumstantial and indirect, making it difficult to make any legitimate claims about intelligence in *A. afarensis*. Still, when looking at skull morphology in *A. afarensis*, it is clear that encephalization, being the relative size of the forebrain and therefore an indirect measure of "thinking capacity," was similar to or slightly larger than that of modern great apes (Begun and Kordos 2004). The amount of encephalization in *A. afarensis* relative to that of modern great apes may be indicative of similar levels of intelligence, making tool use not entirely impossible. However, both the absence of adaptations for precision grasping in *A. afarensis*, as well as the absence of stone tools in the fossil record

anywhere before two million years ago make it highly unlikely that this early hominid was an avid tool user (Susman 1994).

As with intelligence, evidence of the social structure of *A. afarensis* can only be inferred from indirect evidence. In this case, sexual dimorphism, or size difference between males and females, has been the dominant lead. Analyzing skeletal size of male and female specimens has suggested that sexual dimorphism in *A. afarensis* was similar to that in modern humans, providing evidence that male–female dynamics in this species were similar to that of *H. sapiens* and thus predominantly monogamous (Larsen 2003; Reno et al. 2003). However, this claim may be debated due to the fact that different methods have shown that sexual dimorphism in *A. afarensis* may have closer resembled that of modern day great apes (Lee 2005), which suggests a social structure that is more reminiscent of chimpanzees, with males competing over females in cooperative communal groups (Larsen 2003).

## Conclusion

The fossilized remains of both Lucy and her conspecifics have provided novel insights into the realms of human evolution and paleoanthropology. Still, notable information, like that regarding Lucy's mode of locomotion and ecology, remain open for debate. Despite the secrets that Lucy has unraveled about early hominins, specifically *A. afarensis*, uncovering further unpreserved traits such as intelligence, social structure, or mating rituals remain to be uncovered, due to the elusive nature of the evidence provided in the fossil record.

## Ludwig Huber

Ludwig Huber

Messerli Research Institute, University of Veterinary Medicine Vienna, Medical University of Vienna, University of Vienna, Vienna, Austria

## Personal History and Overview of Research

Ludwig Huber was born in Neunkirchen, Lower Austria, on 25 July 1964, but raised in Ternitz. He attended Sachsenbrunn, a classical grammar school near Kirchberg/Wechsel for 8 years, where he was educated in traditional humanistic studies, including Latin and ancient Greek. Despite this catholic-humanistic education, Huber nourished interest in biology from an early age. As a child he dreamed of becoming a biologist, mainly due to his fascination with African fauna (actually by watching TV documentaries and reading books about the work of Jane Goodall, Diane Fossey, and Bernhard Grzimek). Shortly before starting his biology studies at the University of Vienna, he participated in a symposium celebrating the 80th birthday of Konrad Lorenz in Laxenburg (south of Vienna). It was here that he got his first hands-on lessons in ethology from well-known scholars of Lorenz, including Bernhard Hassenstein, Sverre Sjölander, Wolfgang Schleidt, Iräneus Eibl-Eibesfeldt, and Antal Festetics. Still, he was most fascinated by Rupert Riedl, a professor of theoretical biology at the University of Vienna, who was not a scholar but a companion of Lorenz in his later years. His speech drew Huber's attention away from classical ethology and toward evolutionary and cognitive biology.

During Huber's biology studies (major, zoology; minor, philosophy and philosophy of science) at the University of Vienna (1983–1988), he broadened and deepened his interests with a focus first on comparative morphology (homology) and later on evolutionary theory (the debates about group selection, exaptation, and constraints). His latent interest in behavioral biology

was nourished by an excursion to the Maldives, where he compared different foraging strategies of coral reef fish. Nevertheless, he was taken by Rupert Riedl's lectures and seminars on evolutionary epistemology, the most interesting of which being dedicated to an interdisciplinary inquiry into the theoretical foundations of biology. This motivated him to study the philosophy of science (Erhard Oeser) as an accessory discipline with a focus on the Viennese strand of evolutionary epistemology following Ernst Mach, Ludwig Boltzmann, and Karl Popper. Still, the major influence on his later career arose from writings of Konrad Lorenz and Rupert Riedl, most notably the books "Behind the Mirror" and "Biology of Knowledge," and two conferences on evolutionary epistemology, organized by Rupert Riedl at the University of Vienna, with Karl Popper and Konrad Lorenz as keynote speakers.

Shortly after these influential events, Huber started his diploma thesis project, which examined the power of associative learning as a means of anticipating events that do not follow alternation sequences. Indeed goldfish (*Carassius auratus*) proved able to adapt to a complex sequence of reinforced and non-reinforced events. This study was part of Rupert Riedl's larger project dedicated to applied questions of evolutionary epistemology, namely, the parallel working of rational and irrational (called "ratiomorphic") processes in human thinking. Inspired by vivid discussions during two visits of Konrad Lorenz in autumn 1988, Riedl and Huber tested several populations of humans, varying in age and education, on how they distinguish between foreseeable and unforeseeable event series. Surprisingly, with the exception of mathematicians, most participants relied on the "negative recency effect," also known as the "gambler's fallacy."

After completing his diploma studies in biology and philosophy in 1988 (academic title Mag. rer. nat.), Huber turned to a completely different topic for his doctoral thesis, namely, pigeons' (*Columba livia*) ability to categorize complex visual classes. In comparison to students, pigeons solved a polymorphous classification problem (the so-called m-out-of-n problem) by learning to combine the four class-defining feature

dimensions of an artificial stimulus set (so-called Brunswick faces) in an additive manner. Humans have difficulties solving such problems as quickly as pigeons because we tend to try combinations of conjunctive and disjunctive rules. Here again evolutionary epistemology offers an answer in terms of the parallel existence of simpler and more advanced, or in evolutionary terms older and more recent, processes of human cognition. Huber's work on categorization (prototype formation, feature learning) and concept formation (including abstraction and rule learning) remained the focus of his research for more than a decade after graduating (Dr. rer. Nat.) in 1991.

Ludwig Huber had the good fortune to be offered the position of university assistant to Prof. Riedl at the Institute of Zoology (Faculty of Natural Sciences) in 1991 and, after his retirement, became head of the Department of Theoretical Biology for almost 8 years (1995–2003). Huber received the postdoctoral lecture qualification (habilitation) for zoology together with the professional upgrade to associate professor in 2000. Thanks to a successful period of raising third-party funding, and by means of international advertisements, Huber was able to hire qualified young postdocs and PhD students. These enthusiastic colleagues arrived with broad interests and helped to widen his research agenda and raising awareness of the steadily growing unit, its scientific output, and its international visibility, especially through an EU-funded international research project that he coordinated. As a result, his lab received the status of priority research program "Cognition" of the Faculty of Life Sciences in 2005.

Huber's purely noninvasive research program at the University of Vienna (1991–2011) involved many aspects of comparative cognition, clustering mainly around perceptual, social, and technical cognition. Rather than using animals as "model systems" to understand humans, he aimed at understanding the cognitive worlds of animals within an evolutionary context (Heyes and Huber 2000). Perhaps the most fundamental component of cognition is *categorization*. Using improved methodologies, Huber and his co-workers demonstrated that pigeons, though

lacking language and presumably also the associated higher cognitive capacities, can categorize photographs or drawings as complex as those encountered in ordinary human experience (Huber et al. 2005). The underlying cognitive mechanisms include picture memorization, feature learning, prototype formation, and the abstraction of concepts. These topics had already been addressed in Huber's doctoral thesis, but he later added studies on the perception of biological motion (with Niko Troje, Kingston, Canada) to serve social recognition, picture-object equivalence, inference by exclusion, and the functional asymmetry of the pigeon brain (with Onur Güntürkün, Bochum, Germany). In addition to pigeons, the researchers investigated the link between perception and cognition in kea (*Nestor notabilis*), domestic dogs (*Canis familiaris*), red-footed tortoises (*Geochelone carbonaria*), lizards (bearded dragon; *Pogona vitticeps*), archer fish (*Toxotes chatareus*), and giant pandas (*Ailuropoda melanoleuca*).

A second research focus clustered around social learning. This ability is considered an important manifestation of cognitive behavior in both humans and nonhuman species. Huber's main interest focused on the mechanisms underlying learning through conspecific observation and their contribution to the horizontal and vertical transmission of innovations. Rigorous experiments were conducted with marmosets (*Callithrix jacchus*) to investigate *imitation*, i.e., learning some part of the form of a demonstrated behavior (Voelkl and Huber 2000). Imitation, it is said, not only demands the most sophisticated cognitive processes but also enables the most elaborate form of social information transfer, "cultural transmission." The formation of behavioral traditions and possible effects of conformity and habit formation were studied in wild marmosets (with Nicola Schiel and Antonio Souto, Recife, Brasil). Other forms of nongenetic transmission, like *emulation* (i.e., learning about the properties or the function of objects), were studied in kea (with Michael Taborsky, Bern, Switzerland) (Huber et al. 2001). The functional role of observational learning and the learning of sequences was investigated in marmosets as well as dogs (Huber et al. 2009). In addition to evidence for automatic

imitation (with Cecilia Heyes, London, UK) and *deferred* imitation (with Adam Miklosi, Budapest, Hungary), Huber and his team found evidence for *selective imitation* in dogs (with Gyorgy Gergely, Budapest, Hungary) (Range et al. 2007). Cooperation and some underlying social factors (like scrounging tolerance, inequity aversion) were studied in dogs, kea, and marmosets (Range et al. 2009). Concerning the evolution of social learning, they also found surprising evidence for social learning in nonsocial tortoises and lizards (Wilkinson et al. 2010).

The third research focus was directed at physical intelligence. In the inanimate environment, problems arise from the interaction with objects, the understanding of physics (*folk physics*), time, space, and causality. Using the kea as a model, the team investigated how birds manipulate objects in a flexible manner by learning how the objects affect the environment (Huber and Gajdon 2006). Comparisons with marmosets, but also ravens (*Corvus corax*) (with Thomas Bugnyar, Vienna), New Caledonian crows (*Corvus moneduloides*) (with Auguste von Bayern, Oxford, UK), and Goffin's cockatoos (*Cacatua goffiniana*) (with Alice Auersperg, Goldegg, Austria) provided important insights into the selective pressures for the evolution of technical intelligence. Both kea and Goffin's cockatoos showed flexible and innovative behavior, with the individual invention of using a stick tool to act in a goal-directed manner on objects. In collaboration with Elisabetta Visalberghi (Rome), Huber and his colleagues investigated causal understanding in capuchin monkeys (*Cebus apella*) using stones as percussors for nut-cracking behavior.

This extensive research agenda could not have been realized without the establishment of excellent facilities in cooperation with highly motivated collaborators. Firstly, Ulrike Aust and Michael Steurer helped establish a huge pigeon testing facility equipped with half- and fully automatized indoor conditioning units connected to outdoor aviaries for 120 pigeons. Ludwig Huber, along with Thomas Bugnyar and Bernhard Voelkl, established a marmoset lab with indoor/outdoor enclosures for two to three families of up to eight individuals each. Huber and Gyula

Gajdon improved the outdoor facilities for kea (the mountain parrots of New Zealand) at the Konrad Lorenz Institute for Ethology. In 2007 Huber founded, with colleagues Friederike Range and Zsófia Virányi and the generous help of a private sponsor, the first Clever Dog Lab in Vienna. And finally, Anna Wilkinson's vision and enthusiasm made possible the creation of the "Cold Blooded Cognition" Lab in 2008, including indoor facilities for tortoises, lizards, and tadpoles.

In parallel to his research, Huber's teaching interests were also broadened, with lectures and courses ranging from animal behavior and cognition to comparative morphology, evolutionary biology, and even bioethics. He gave comparative cognition lectures not only at the University of Vienna but also as a guest professor at the Charles University in Prague (2005–2011) and at the University of Salvador de Bahia, Brazil (2012). Of course, supervision comprised the majority of his teaching work, helping students on their way to becoming young scientists in more than 80 diploma or master projects and 30 doctoral or PhD projects.

In 2009, he helped recruiting two professors of cognitive biology (Tecumseh Fitch and Thomas Bugnyar) and with them established a new organizational unit, the Department of Cognitive Biology at the Faculty of Life Sciences. As its head from January 2010 to September 2011, Huber was responsible for founding a new research facility 40 km south of Vienna (the Haidlhof Research Station for Cognition and Communication Research) in cooperation with the University for Veterinary Medicine Vienna. In huge aviaries, altogether comprising 1300 m<sup>2</sup>, Thomas Bugnyar's and Huber's groups began comparative investigation of the social and technical abilities of corvids and kea (with Gyula Gajdon and Raoul Schwing). Furthermore, Tecumseh Fitch established research on the vocal production and perception of birds and mammals in specially equipped bioacoustics facilities.

In September 2011, Ludwig Huber was appointed professor of the Natural Science Foundations of Animal Ethics and Human-Animal Interactions at the new Messerli Research

Institute, an interdisciplinary institution of the University of Veterinary Medicine Vienna, the Medical University of Vienna, and the University of Vienna. He was the head of comparative cognition and acted as the institute's spokesperson from its founding until 2014. This appointment allowed him to extend his previous work to the study of emotional processes like empathy, as well as to applied research, in particular on human-animal interactions and ethical issues (e.g., Müller et al. 2015). The range of study species extended to include some exotic species, which Huber and his team investigated in the lab and the field (Goffin's cockatoos with Alice Auersperg in Indonesia and poison frogs with Eva Ringler in French Guiana) and finally also farm animals (pigs, horses, chicken), which they started to investigate in semi-natural conditions (with Marianne Wondrak). Finally, Huber's theoretical interests opened the question of how our understanding of cognitive and emotional processes in animals contributes to our concern and responsibility for them. He became convinced that the better people understand how animals think, decide, suffer, cooperate, reconcile, have empathy and theory of mind, etc., the more they will be inclined to respect and take care of them, i.e., take responsibility in the various forms of human-animal interactions and include them in our moral universe.

## Lunate Sulcus

Vishwajit Ravindra Deshmukh<sup>1</sup> and  
Dinesh Kumar<sup>2</sup>

<sup>1</sup>Department of Anatomy, All India Institute of Medical Sciences, Nagpur, Maharashtra, India  
<sup>2</sup>JIPMER, Puducherry, India

## Introduction

Sulci are defined as deep portions on the surface of the cerebral hemisphere. The cerebral cortex is divided into the five lobes with the help of the major sulci present on the surface. The central sulci divide the cortex into frontal and parietal lobe, the lateral sulcus or fissure divides the superolateral surface into upper parietal and lower temporal lobe. The imaginary line joining the parieto-occipital sulcus and pre-occipital notch, situated 5 cm anterior to the occipital pole mark the occipital or the posterior region. The major concern of the occipital lobe is the visual information receiving and processing.

Lunate sulcus also called as “ape sulcus” was first identified by the anatomist Grafton Elliot Smith on the posterolateral part of the brain. It was identified to be a feature of the ape brain but not exclusively persistent with them instead can be markedly present in human brains also. In its typical forms, lunate sulcus is situated just in front of the occipital pole which may or may not be joined by the calcarine sulcus and oriented vertically (Allen et al. 2006). However, the frequency of description differs between right (26.4%) and left side (32.7%) (Allen et al. 2006).

The location of lunate sulcus as compared to the apes is located more posteriorly. According to Smith Elliot, this lunate sulcus forms important landmark to identify the band of Gennari. According to his observation, the sulcus is not a permanent and symmetrical feature of the ape as well as the human brain.

## History and Evolution

Lunate sulcus has been linked as an important milestone with the discovery of Taung baby, *Australopithecus africanus*, in the evolution by the Raymond Dart, the former student of Elliot Smith. In his evaluation, he identified that the location of lunate sulcus is more posteriorly placed in humans than apes, suggesting the increased surface area for the parietal, temporal, and occipital lobe. Thus the position of the lunate sulcus forced data to conclude that Taung baby was not simply an extinct ape but the evolutionary modified early hominid.

Some evidence to confirm its evolutionary profile was given by Falk et al. in 2005. He also identified the location of the lunate sulcus more posteriorly placed in the homo floresiensis specimen and also argued that despite such a small brain volume; there were high cognitive processing abilities.

In order to assess the actual evolutionary profile of the lunate sulcus, the same sulcus was studied the contemporary species, i.e., chimpanzee. In them, the sulcus is a prominent feature with a particular location and present as a deep sulcus and thus marking the position for the anterior extension of the occipital lobe. However, after recent finding in the two chimpanzees, the lunate sulcus is more posteriorly placed as compared to the fellow chimps, correlating the human-chimpanzee common ancestral evolutionary origin with more cognitive capabilities. Thus, it is evident that posteriorly positioned lunate sulci in the fossil hominis is an indicator for reduction in the volume of primary visual cortex and this is due to the evolutionary up gradation of the visual association areas. Presumably, this would have resulted from the functional reconfiguration since the period of *Australopithecus africanus* (Holloway et al. 2001). Larger brains having significant number of visual association areas process the primary information obtained by visual cortex and delegate them to visual association areas for further processing.

Holloway RL performed a profound research regarding the lunate sulcus and found that it was much better defined in the anthropoid humans other

than humans and in those species, it demarcates the anterior boundary of primary visual cortex (Holloway 1975). When compared to anthropoid brains, human lunate sulci are fragmented in nature with a significant posterior displacement (Holloway et al. 2001, 2003). Studies have shown that the human brains which lacked prominent lunate sulcus had reduced volume of primary visual cortex (Ono et al. 1990).

## Shapes of the Lunate Sulcus

The variability in the occipital sulcus is more and extensive. It may appear as a continuous structure or fragmented or segmented in some of the specimens. The combination of these fragmented segments was referred to as composite lunate sulcus. According to Allen et al., lunate sulcus were classified as complete, composite, or no lunate sulcus. The composite sulcus is much more common than the individual complete sulcus. Connolly's also grouped the lunate sulcus into various groups depending upon the segmentation or continuous nature. In general, Elliot's Smith observed that there was a rare similarity in the two cerebral hemispheres of the same individual. In some of the research articles showed the presence of lunate sulcus is more in the left side as compared to the right side of the cerebral hemisphere. In addition, lateral occipital sulcus, otherwise known as pre-lunate sulcus is crucial for defining the overall morphology of the lateral surface of occipital lobe and divides the lobe into superior and inferior portions (Smith 1904).

Malikovic and colleagues (2012) found that out of 30 hemispheres, lunate sulcus can be observed as a variable but continuous impression near the occipital pole and mostly there were either seen as continuation of inferior lateral occipital sulcus (6/10 hemispheres) or superior lateral occipital sulcus (4/10 hemispheres). They concluded that lunate sulcus is not homologous among humans and primates.

In some of the great apes, the lunate sulcus is so deep that it will form an occipital operculum, but in

humans, the finding is not evident. Initially it was thought that lunate sulcus is related to the visual cortex, but later extensive studies were done to map the visual areas in the cerebral cortex. However, it needs to be remembered that in contrast to the higher degree of gyrification in rest of the human cortex, occipital lobe of apes have similar degree of gyrification as humans (Armstrong et al. 1991).

## Machiavellian Intelligence

Richard W. Byrne  
Centre for Social Learning and Cognitive  
Evolution, School of Psychology and  
Neuroscience, University of St Andrews,  
St Andrews, Scotland, UK

### Synonyms

[Social intelligence](#)

### Definition

The hypothesis that an important contribution to the evolution of intelligent behavior was the adaptive challenge of dealing with the complexities of living in a social group: striking a balance between cooperation and competition with a range of other individuals, often requiring subtle social skills rather than brute power.

### Introduction

Before the 1980s, it was generally accepted that intelligence, in the sense of that package of useful skills that impress people as being in some way “smart,” evolved to deal with the physical challenges of the environment: finding and getting access to food, remembering safe places, noticing

signs of danger, etc. (For human evolution, a special form of this hypothesis was labeled “Man the tool maker.”) Complex societies were considered a by-product of intelligence.

Radically different views were occasionally expressed, pointing instead to the problems set by social living. Chance and Mead (1953), impressed with the social maneuvering of male baboons, suggested that social challenges might select for greater intelligence in general. Alison Jolly (1966), pioneering the study of highly social lemur species whose members seemed technically inept, suggested reversing the common view of primate society as a product of intelligence, postulating instead that general intelligence might result from the complexity of social living. Nicholas Humphrey (1976), a psychologist highly experienced with the skill of captive monkeys in dealing with experimenters’ gadgetry, could see nothing remotely as challenging in their natural environment and made a strong case that they met greater problems simply by living socially; he therefore proposed that intelligence might result, as an adaptation to group living, itself driven by other factors such as reduction of predation risk. Noting that these radical proposals had emerged at roughly decade intervals, Byrne and Whiten (1988) argued that this was an idea whose time had now come and put together a book which reprinted those seminal theory papers plus a range of current studies that gave support to the hypothesis, which they labeled “Machiavellian intelligence” and used as the book’s title.

The apposite nature of Niccolo Machiavelli's maxims to describe the social maneuverings of nonhuman primates was first pointed out by Frans de Waal, who chose Machiavelli quotations to explain the logic of chimpanzees' "political" decisions about social alliances (de Waal 1982). In giving advice to an aspiring prince, Machiavelli (1532/1979) had stressed the importance of being friendly, cooperative, kind, and generous – just until it paid not to be so. Similarly, the Machiavellian intelligence (MI) hypothesis applies just as much to the social sophistication shown in friendship formation, reconciliation, coalitions and alliances, kin support, and reciprocal altruism, as it does to deception and overtly political manipulation. Old World monkeys, for instance, use grooming to build up relationships with unrelated individuals who later come to their aid in conflicts (Dunbar 1991); if important monkey friendships are disrupted by a fight, one of the combatants will soon make friendly overtures which usually result in repairing the relationship (Cords 1992); if a monkey's relative or ally is attacked by a high ranker, then they may still respond – by attacking a (lower-ranking) relative of the attacker, in a sort of monkey vendetta (Seyfarth and Cheney 1984). Individuals sometimes use deception tactically, such as when a young monkey, frustrated by seeing a larger individual monopolizing a good food source, gives a scream that causes his higher-ranking mother to rush to his aid and displace the other monkey: "coincidentally" leaving the food source for the youngster to monopolize (Byrne and Whiten 1985; Whiten and Byrne 1988). All this implies a great deal of social knowledge, about who's a friend or relative of whom, and this knowledge is often acquired indirectly, by "eavesdropping" on conflicts among third parties, as primatologists have shown by simulating conflicts with artfully constructed sequences of monkey calls (Kitchen et al. 2005). The ultimate benefits are selfish; the proximate means may be altruistic, or not. MI should therefore not be conflated – though it sometimes has been – with the human personality trait of "Machiavellianism" (Christie and Geis 1970), which refers specifically to an ability

to detach from conventional morality and emotionality in order better to deceive and manipulate other people. MI is not about morality and not restricted to "nasty" actions. Using the synonym "social intelligence" does avoid such confusion, but brings in turn the risk of missing the importance of selfish benefit to the agent or its kin in MI – unlike the case of so-called "pro-social" actions – which would be equally misleading.

## Testing the MI Hypothesis

There is no doubt that MI gave impetus over the last 30 years to the great burgeoning of studies on animal social complexity and maneuvering, and it became accepted as a central explanation for the evolutionary origins of intelligence. Clear evidence in support of that position has been more elusive. Part of the difficulty with testing the MI hypothesis relates to ambiguities of its scope (Byrne 1996a; Whiten 1997). Is MI required to be the primary driver of cognitive advance and therefore refuted by any clear cases where it is not? If, instead, MI is just one of many factors that may select for intelligence, interpreting findings is more problematic. Is MI supposed to select for a specific "module" of advanced social intelligence, contrasting with primitive abilities in other domains? If, instead, the result is going to be general intellectual advance, then tying it back to a social origin is much more difficult: how can we be sure which arena was the evolutionary driver of intelligence manifest in many correlated ways? Separating "arenas of expertise" is itself tricky: if acquiring a valuable feeding skill is aided by observational learning from a companion, is that a social or a physical aptitude? At its most general, MI must surely predict that any highly social species should be more intelligent than an asocial one, other things being equal: but when are they equal? If the relatively solitary orangutan consistently outperforms the obligate social baboon, does that refute the MI hypothesis because both are primates – or not, because one is an ape and the other a monkey? To cap these difficulties, the long history of trying to measure differences of

intelligence among animal species gives little confidence that even clear formulations can be tested against reliable data (Macphail 1985).

Researchers instead turned to brain measurements, as a proxy measure of intelligence; but this approach also has its problems. While few would doubt that brain size has some relation to cognitive abilities, pinning down any such relationship so that it can be used as a measure is not straightforward. Like many biological parameters, brain size increases with body size; the relationship is generally curvilinear in group of related species, so plotting on logarithmic coordinates has been used to produce a straight line (allometric scaling). Larger or smaller brain sizes than expected are deduced from (1) the intercept with the Y-axis (height of line), compared with that of other taxonomic groups plotted, and (2) by deviations from the averaged line of a single taxonomic group under examination. As if this were a sort of IQ test, the ratio of observed to expected brain size – the “encephalization quotient” EQ – has sometimes been treated as species intelligence, on the assumption that the brain is in some way an “on-board computer” and bigger is better. Using EQ, it appears that it is diet complexity – among primates, frugivory rather than folivory – that correlates with brain enlargement, rather than any measure of social complexity (Clutton-Brock and Harvey 1980; DeCasien et al. 2017).

However, experience with man-made systems suggests that the upper limit of computing power is given by the *absolute* number of components, whereas the EQ measures brain size *relative* to body size (Byrne 1996b). In consequence, two species with identical EQs but different body sizes can vary massively in the number of extra neurons they possess, above or below that predicted from their body size. Rather than giving a direct indication of intelligence, EQ seems instead to measure cost. The brain is a metabolically expensive organ and requires energy remorselessly at normal temperatures, so the larger the brain the higher the risk to an animal. Larger-bodied species can “afford” larger brains, since their basal metabolic rate will in general be higher, but any species with a brain larger than expected from its body (i.e., high EQ) must have been

under selection for brain size increase; those species with low EQ have been able to manage with smaller brains and thus reduce their costs. Powerful selection for larger or smaller brains certainly gives a clue about the need for cognition, but potential intellectual power is better measured by absolute number of computing components.

Numerous studies in a range of mammalian taxa have found positive correlations between absolute brain size (or absolute size of the neocortex or the ratio of neocortex size to the rest of the brain) and measures of social complexity, which are taken to support the MI hypothesis (Barton and Dunbar 1997). For species that live long-term in stable social groups, the average size of semi-permanent social groups is typically used as a rough-and-ready index of the social complexity confronting any individual. Much of the early work was carried out on primates, whose groupings are typically long lasting and in which researchers have shown that relationships are differentiated: an individual knows others as individuals and behaves quite differently toward them according to their kin relationships, friendships, and history of past interactions with them. These characteristics are critical for the Machiavellian intelligence hypothesis, because it is only when relationships are differentiated among individuals that there is any real possibility of social complexity. Many groupings of mammals and birds are temporary aggregations, such as a winter flock of sparrows and finches foraging near a grain store or a herd of deer feeding on a flush of young grass. Their typical group size is not predicted by MI to relate to any measures of brain size, and indeed they do not (Dunbar and Shultz 2007; Emery and Clayton 2005). But for primates, and for several other mammalian families which live in semipermanent groups, such as cetaceans and chiropteran bats, correlations with brain measures have regularly been found.

Unfortunately, absolute brain size is itself flawed as a proxy measure of intelligence. Many brain functions do not contribute to the package of abilities we recognize as intelligence, but rather regulate the somatic and sensory functioning of the body; those functions are presumably responsible for the strong relationship between brain size

and body size, so often noted. Harry Jerison (1963, 1973), the pioneer of the allometric approach to intelligence, was well aware of the problem. He tried to devise a measure of “spare neurons” – the computing capacity, measured in neural components, beyond that which an animal needs minimally for regulatory functions and therefore available for cognitive computations. So far, no generally accepted measure of spare neural capacity has been found. The size of individual neurons and their packing density vary across species and larger taxonomic groups, and these variations can be compensated for: but the fundamental problem remains that neither the brain nor any specific brain part is a dedicated “thinking machine,” and we have no principled way of taking account of all the other demands on neural capacity in addition to any cognitive computing. Until one is found, claims that the MI hypothesis has been proven or refuted must be taken with a large pinch of salt.

### What Is Social Complexity?

At the heart of the MI hypothesis lies the idea of social complexity and the belief that we can compare it with other kinds of complexity confronting individual animals (Byrne et al. 2001; Cochet and Byrne 2014; Sambrook and Whiten 1997). Traits accepted as indicating social complexity among primates, and increasingly discovered in other taxonomic groups, include acquisition of rank by kin support; the use of grooming to cultivate “friendships” with potentially useful individuals, friendships that persist over long time scales and predict the distribution of mutual help; as a consequence, the important role of third parties in deciding the outcome of conflicts; informed choice of potential allies on the basis of individual characteristics; and the repair of these relationships by targeted reconciliation after conflict. These traits are generally species-typical, so likely to be strongly channeled genetically. To benefit from such “hard-wired” traits, individuals must possess certain fundamental cognitive capacities: (1) distinguish conspecific group members as individuals and respond differently to kin,

(2) remember relative ranks and past affiliations, and (3) remember the personal histories of help given and received from various others (Byrne 2016). Manipulation by tactical deception is reported only among certain individuals and varies in precise form even within a species. Nevertheless, most records of deception can be explained as learning from natural coincidences, provided individuals first possess a rich database of social knowledge and can learn new tactics over only a very few trials (Byrne 1997b). Success essentially demands good visual perception and discrimination, attention to social attributes, and a good memory. Confronting situations of increased social complexity is therefore likely to select for enhanced social discrimination and memory efficiency, including rapid learning of socially relevant information.

The word “understanding” is conspicuously absent in this account. Of course, an individual able in some way to represent and compute with what is going on in the mind of a competitor or an ally would be viewing a more complex situation. Evidence that such mentalizing or “theory of mind” understanding is found in animals has been controversial, but is now becoming accepted for a few animal species, including all great apes and some corvid and psittacine birds, and possibly also toothed whales and elephants (Byrne 2016). It does not appear possible to explain such a distribution by invoking the MI hypothesis (Byrne 1997a). Using the rough-and-ready metric of the average size of semipermanent groups, great apes cannot be confronting greater social challenge than many monkey species, several of whom live in larger groups than any ape. Similarly, corvids and parrots do not live in particularly large groups: monogamous pairs are typically the largest long-term associations among birds, and those few species living in larger groups, often cooperative breeders, seem in any case to have smaller brains (Fedorova et al. 2017).

### Conclusion

The Machiavellian intelligence hypothesis that social complexity is a powerful driver of selection

for cognitive power in animals is consistent with the social sophistication and manipulative tactics that have been increasingly documented among animals in the last 50 years. Direct testing of the hypothesis will require good measures of intelligence that can be applied across species and clearer statements of what exactly MI and competitor hypotheses predict, both of which have been lacking. Most social complexity among animals can be underpinned simply by good skills of memory and perception, allowing rapid learning of nuanced distinctions among social companions. While a good case can be made that this quantitative variation matches the challenge of living long-term in larger social groups, that is not the case for mentalizing about others (theory of mind), whose distribution does not particularly correlate with living in large groups.

## Major Histocompatibility Complex

Reema Chaudhary

Molecular Biology Division, Bhabha Atomic Research Centre, HBNI, Mumbai, India

### Synonyms

[Human leukocyte antigen \(in humans\) and H-2 \(in mice\)](#)

### Definition

A tightly linked cluster of genes present in every mammalian species called as major histocompatibility complex (MHC).

The functions of the products of this complex are intercellular recognition and discrimination between self and non-self. MHC genes are of fundamental significance in both types of immune responses (i.e., humoral and cell-mediated) to foreign proteins. Recognition of antigens by T cells happens only when it is combined with an MHC molecule whereas antibodies react with antigens alone. The repertoire of antigens recognized by T helper ( $T_H$ ) and T cytotoxic ( $T_C$ ) cells is influenced by expression of particular set of MHC molecules in an individual.

### Mouse and Human MHC Loci

The MHC is a collection of genes located on the short arm of chromosome 6 in humans and on chromosome 17 in mouse. The MHC is referred to as the HLA (human leukocyte antigen) complex in humans and as the H-2 (histocompatibility-2) complex in mice (MHC sequencing consortium 1999). The organization of MHC genes into regions encoding three classes of molecules in the mouse and human is shown in simplified form in Fig. 1.

The products of different classes of MHC genes are as follows:

| Complex   | H-2 (in mice)       |                     |                     |                     |       |       |       |
|-----------|---------------------|---------------------|---------------------|---------------------|-------|-------|-------|
| MHC Class | I                   | II                  |                     | III                 | I     |       |       |

**Major Histocompatibility Complex, Fig. 1** Simplified organisation of MHC genes in mice and humans

Class I MHC genes encode glycoproteins which are expressed on the surface of nearly all nucleated cell. These molecules are encoded by the K and D regions in mice and A, B, and C loci in humans and referred to as classical class I molecules. Other genes which also encode class I molecules within the H-2 or HLA complexes are referred to as nonclassical I genes. Class I MHC molecules play a role in presentation of peptide antigens to T<sub>C</sub> cells.

Class II MHC genes encode glycoproteins which are expressed on antigen-presenting cells (macrophages, dendritic cells and B-cells). These molecules are encoded by the IA and IE regions in mice and DP, DQ, and DR regions in humans. Class II MHC molecules play a role in presentation of peptide antigens to T<sub>H</sub> cells.

Class III genes encode molecules that function in immune responses which includes complement components and inflammatory cytokines (TNF) and cytokines.

### Inheritance of Alleles of MHC Genes in Linked Groups

MHC locus is highly polymorphic which means there are many forms of the genes or alleles existing at each locus among a pool of population. The recombination frequency within the complex is  $\leq 0.5\%$  indicating the linkage of genes of MHC locus. Inheritance of set of these genes occurs in

linked groups referred to as haplotype (a single set). A person inherits one haplotype from the father and other one from the mother. MHC locus is generally heterozygous in outbred population and codominant, i.e., both maternal and paternal alleles are expressed in an individual. If mice are inbred (having identical alleles at all loci), H-2 locus will be homozygous and both maternal and paternal haplotypes are identical.

## MHC Molecules

### Class I MHC

The structure of both class I and II molecules have been determined by x-ray crystallography. Class I MHC molecule is composed of a 45 kilodalton (kDa)  $\alpha$  chain and a 12 kDa  $\beta$ 2-microglobulin molecule. The  $\alpha$  chain is a transmembrane glycoprotein encoded by genes in the A, B, and C regions of the human HLA complex and K and D/L regions of the mouse H-2 complex.  $\beta$ 2-microglobulin is a protein encoded by gene present on a different chromosome. For expression of class I MHC molecules on cell membranes, association of the  $\alpha$  chain with  $\beta$ 2-microglobulin is required. The  $\alpha$  chain is organized into three external domains ( $\alpha$ 1,  $\alpha$ 2 and  $\alpha$ 3), a hydrophobic transmembrane domain and a hydrophilic cytoplasmic anchor segment. The  $\beta$ 2-microglobulin shows similarity in organization to the  $\alpha$ 3 domain, lacks a transmembrane

**Major Histocompatibility Complex, Fig. 2** The pictorial representation of MHC molecules

region, and binds to the class I glycoprotein noncovalently (Fig. 2). The peptide binding cleft is formed by the interaction of  $\alpha 1$  and  $\alpha 2$  domains and located on the top surface of the class I MHC molecule and it is large enough to bind a peptide of 8–10 amino acids as this is blocked at both ends (Natarajan et al. 1999).

### Class II MHC

Class II MHC molecule consists of two different polypeptide chains, a 33 kDa  $\alpha$  chain and a 28 kDa  $\beta$  chain. Both  $\alpha$  and  $\beta$  chains have two external domains ( $\alpha 1$ ,  $\alpha 2$  in one chain and  $\beta 1$ ,  $\beta 2$  domains in the other), a transmembrane segment, and a cytosolic anchor segment (Fig. 2). The  $\alpha 1$  and  $\beta 1$  domains interact to form antigen binding cleft. This cleft present as an open-ended groove and binds to a peptide of 13–16 amino acids (Owen et al. 2013).

### MHC-Peptide Interaction

Allelic forms of class I and II MHC genes are polymorphic and in humans several hundred different allelic variants have been identified. But only 6 different class I molecules and up to 12 different class II molecules are expressed, despite of this number MHC molecules are able to present a wide variety of different antigenic peptides to T cells. The binding between a peptide and an

MHC molecule is referred to as promiscuous because a given MHC molecule can bind numerous different peptides and some peptides can bind to several different MHC molecules.

Class I MHC molecules present peptides to CD8<sup>+</sup> T cells. These peptides are derived from endogenous intracellular proteins that are digested in the cytosol, and then transported from the cytosol into the cisternae of the endoplasmic reticulum, where they interact with class I MHC molecules. This process is known as the cytosolic or endogenous processing pathway (Abbas et al. 2014).

Each allelic variant of a class I MHC molecule binds a distinct set of peptides and about  $10^5$  copies of each class I MHC molecules are expressed on the surface of a single nucleated cell enabling it to present different peptides simultaneously. The peptides which bind to these MHC molecules have two features:

- Peptide length is 8–10 amino acids.
- They contain specific amino acid residues which anchor the peptide into groove and called as anchor residues.

Class II MHC molecules presents peptides to CD4<sup>+</sup> T cells. It also binds to a variety of peptides which are derived from exogenous proteins (either self or nonself), internalized by phagocytosis or by receptor-mediated endocytosis, and

processed by the endocytic processing pathway. Peptides binding to class II MHC molecules are generally 13–18 amino acids and contains internal conserved motif unlike anchor residues in class I MHC molecules (Hennecke et al. 2000). This internal sequence comprises of 7–10 amino acids that provide the major contact points. This sequence has aromatic or hydrophobic residues at the amino terminus and three additional hydrophobic residues in the middle portion and carboxy-terminal end of the peptide (Owen et al. 2013).

## Conclusion

A wide range of different MHC molecules are expressed in an individual and within a species. The source of diversity in antibodies and T-cell receptors is somatic process including gene rearrangement and somatic mutations whereas MHC molecules diversity originates from polymorphism. Sequence variation among alleles of the MHC within a species is very high but not randomly distributed along the entire polypeptide chain, rather clustered in short stretches, mainly within the membrane distal  $\alpha 1$  and  $\alpha 2$  domains of class I molecules. Interestingly,  $\alpha 1$  and  $\beta 2$  domains of class II molecules also show similar patterns of diversity. Some alleles occur at a much higher frequency in those suffering from certain diseases than in the general population. The diseases associated with particular MHC alleles include autoimmune disorder, some viral diseases, several allergies, disorders of complement, and neurological system. A relative risk is a value which is calculated by determining the frequency of the HLA alleles expressed by the patient and then comparison of this data with the frequency of the same alleles in the normal population. This value basically tells the association between HLA alleles and a given disease.

## Margaret Floy Washburn

Rachel T. Walker  
Department of Psychology,  
University of the Incarnate Word,  
San Antonio, TX, USA

Margaret Floy Washburn (July 25th, 1871 – Oct. 29th, 1939) played a major role in the advancement of Comparative Psychology, in regard to humans and non-humans. In addition, she assisted in the revolution of women in the field of psychology. She was the second woman to serve as the American Psychological Association (APA) president in 1922 and also was the second woman to be named as a Fellow of the National Academy of Sciences in 1931 (Woodworth [1949](#)).

She first began her undergraduate degree at the age of 16 at Vassar College (1891). When she completed her degree she was interested in attending Columbia University under the guidance of James McKeen Cattell. During this time women

were not able to apply for the graduate program. She spent one year as a student auditor learning under the direction of Cattell. He suggested that she apply to Cornell University. Cornell accepted her in 1892 and she worked under the direction of Edward B. Titchener not only as his first female student but also his first graduate student in his lab. Within her first year in the program she was able to use the research she had collected with Cattell to get a Master's degree from Vassar College. She was the first woman to be awarded her PhD, studying cutaneous perceptions from the perspective of distance and direction, a few years later from Cornell in 1894. After graduating she worked as the Chair of Psychology, Philosophy and Ethics at Wells College from 1894 to 1900. She then spent two years back at Cornell as a lecturer of Psychology in addition to being a warden at Sage College for women. In 1902 she spent one year at University of Cincinnati before she became a professor at Vassar College and stayed there for 36 years (Woodworth 1949). Her areas of interest were not only in psychology but a variety of other disciplines such as philosophy, chemistry, biology, and art.

One of Washburn's major contributions included consciousness in humans and non-humans (*The Animal Mind*, 1908). Throughout this book she summarized experimental studies on a variety of topics such as sensory perception, consciousness, and attention. This contribution was successfully used by other professors for many years later. The book was updated and published in later editions (in 1917, 1926, and 1936) as new research was explored in the field. Another contribution was related to motor development as it pertained to the Motor Theory. In the book, *Movement and Mental Imagery* (1916), the question was asked about how consciousness plays a role in motor movement. More specifically, how is this related to the perception of movement from a distance and modification of the responses to that perception? Within the topic she explored the importance of motor movements in the context of learning and attention. From a retrospective view she contributed to knowledge on spatial perception, binocular rivalry, afterimages, memory of hand movement

and emotions, individual differences, color vision motivation, and orientation across a variety of species (Woodworth 1949). Her contributions to experimental research, editorial and reviewer roles, and leadership have displayed her insight and determination.

## Margaret Ruth Kuenne Harlow

David A. Washburn

Covenant College, Lookout Mountain, GA, USA  
Georgia State University, Atlanta, GA, USA

Margaret Ruth (nee Kuenne) Harlow (August 8, 1918 – August 11, 1971) was a child psychologist and primatologist best known for her decades of research collaboration with husband Harry F. Harlow. She also contributed extensively to the field through editorial work and helped to establish the American Psychological Association Publication Office, serving as its first director. Her expertise in child development was critical in the Harlows' well-known studies on the effects of maternal separation, social deprivation, and contact comfort on infant monkeys' social, cognitive, and behavioral competencies. Margaret Harlow's research not only illuminated the importance of parental care in the development of

primate infants but also served as a model for the integration of developmental and comparative frameworks in psychological science and theory.

Margaret Ruth Kuenne was born in St. Louis, Missouri. Her parents were Edward S. (a newspaper compositor) and Margaret E. Kuenne (a milliner). She was the eldest of three siblings, each of whom would grow to attain academic prominence: brother Robert E. Kuenne (1924–2005) would become a noted economist at Princeton, and sister Dorothy J. (Kuenne) Stearns (1927–1972) would earn her doctorate in chemistry before working in atomic physics at Washington University. Among the siblings, Margaret Ruth Kuenne was first to obtain a Ph.D., earning hers in psychology from the State University of Iowa (1944). Previously, she received bachelor's and master's degrees at Washington University in St. Louis (1938 and 1940, respectively). She was a member of national honor societies both at Washington (Phi Beta Kappa) and at Iowa (Pi Lambda Theta). In her dissertation, directed by Kenneth W. Spence, Kuenne reported an experiment she conducted as a research assistant in the prestigious Iowa Child Welfare Research Station. The study, subsequently published in the *Journal of Experimental Psychology* (Kuenne 1946) was an investigation of transposition by 56 preschool and kindergarten children (3–6 years of age). The work provided an important theoretical bridge between the animal research in the Spence tradition on the one hand and the verbal behavior thought to mediate transposition by human adults on the other. She found that as mental age increased, and thus verbal labels like “bigger” and “smaller” became more available, children were more likely to pass the most difficult of transposition tests. The dissertation has been described as “a classic in the area of children's learning” (Graham et al. 1971). University of Michigan educational psychologist Harold W. Stevenson described Kuenne's doctoral project as “. . . a lucid example of how theoretically based research could be conducted with children” to bridge the chasm between developmental and comparative literatures (quoted in Graham et al. 1971, p. 1312).

During her time at Iowa, Kuenne also trained as a clinical psychologist and worked in this area after earning her doctorate (Pelcowitz 2012). Her first academic appointment was at the University of Minnesota (1944). In 1946, she moved to the University of Wisconsin in Madison as an assistant professor of psychology. There, Dr. Kuenne quickly published her dissertation, as well as two book reviews in *Psychological Bulletin*. She also began a collaboration with fellow faculty member Harry Harlow, testing children to complement data he was collecting with monkeys. Professor Kuenne remained at the University of Wisconsin for the remainder of her too short but remarkable life and productive career.

However, her career trajectory was not to be without detour. The challenges so often faced by women scholars with respect to academic-/personal-life balance are well illustrated in Dr. Kuenne's biography. A growing mutual attraction with her collaborator and colleague would force Dr. Kuenne to make a choice. As Deborah Blum (2002) wrote about Harlow and Kuenne: “They were natural collaborators, and after Harry's first marriage fell apart, their relationship shifted almost effortlessly into something more intimate.”

On February 3, 1948, Kuenne married Harlow at a quiet ceremony in Anamosa, Iowa. The elopement was in strategic deference to the strict anti-nepotism policies at Wisconsin that forbade such relationships. Harry and “Peggy” (as he called her) Harlow would spend the next 23 years together, until her death. Together, they would have two children: Pamela (1950) and Jonathan (1953). However, the secret marriage became public long before the child psychologist gave birth to children of her own. (Indeed, their “Harlow & Harlow” publication together – a 1949 *Scientific American* article titled “Learning to Think” – described them as husband and wife, both with faculty appointments in the same department.) Soon after the wedding, the Harlows were informed by the university that at least one would be required to resign. Consequently, Dr. Margaret Harlow yielded her faculty position, although she remained professionally active as a project associate in the University of Wisconsin

primate laboratory that her husband directed. She assumed the role of laboratory editor (and, in many ways, day-to-day lab manager) for Harry and his students. When Professor Harlow became editor of the *Journal of Comparative and Physiological Psychology* in 1951, she expanded this role to assist with the editorial duties of that journal, for the duration of his tenure. “Harry always said that Peggy was the more ruthless editor. He told his students that it sometimes took him weeks to persuade her to approve what even he had written” (Blum 2002).

It would be 17 years before Dr. Margaret Kuenne Harlow would again hold an academic appointment. In 1965, she was permitted to return to teaching as a lecturer in the Department of Educational Psychology at Wisconsin. In 1970, she was promoted to professor – achieving her goal of teaching as a full professor before her untimely death.

Despite these professional challenges, Dr. Margaret Harlow contributed richly to the field of psychology, both with achievements in scholarship as well as in administration. In addition to the publications discussed above, she co-authored a paper showing that monkeys learn to solve puzzles in the absence of traditional rewards, suggesting that monkeys have a powerful and primary “manipulation drive” (Harlow et al. 1950). Harlow et al. (1960) published a report of infant monkeys’ performance on learning set and other tasks. Her most impactful scholarly publications, however, came as part of the long-time collaboration for which her husband is principally famous. The studies of maternal separation, social deprivation, contact comfort, and filial affection were critical, if controversial, contributions. Demonstrations of the deleterious behavioral, cognitive, social, and psychological consequences of maternal separation are as important today as they were a half-century ago when they were first and widely reported by Harlow and Harlow. Co-authored publications with titles like “Social deprivation in monkeys” (1962), “The effect of rearing conditions on behavior” (1962), “The affectional systems” (1965), “Maternal behavior of rhesus monkeys deprived of mothering and peer associations in infancy”

(1966, with Dodsworth & Arling), “Developmental aspects of emotional behavior” (1970), and “Psychopathology in monkeys” (1971) showed how effectively and productively science could be advanced through the marriage of developmental and comparative psychology. Summarizing many of the findings from this research tradition – and reflecting Margaret Harlow’s longtime interest in clinical psychology, Harlow et al. (1971) published “From thought to therapy: Lessons from a primate laboratory” in *American Scientist*.

Professor M. Harlow’s last sole-authored publication was a 1971 apparatus paper, describing methodological innovations permitting her to study the developmental consequences for monkeys of rearing in nuclear (mother-father-child) families. About her efforts to study the paternal effects on development, Frances Graham (a former Division 6 President) and her co-authors wrote, “Once again, an important area of behavior, generally thought not to be amenable to laboratory study, succumbed to Harlow ingenuity” (Graham et al. 1971, p. 1314). Sadly, Margaret Harlow did not live to see this work completed.

In addition to these scholarly achievements, Professor Margaret Kuenne Harlow had a lasting professional impact from her service to the discipline. Already discussed was her many years of assistance as editor of *JCPP*. She is also credited with establishing the American Psychological Association Publications Office in 1950, serving as its first director. From 1966 until her death, she was Executive Officer of the Society for Research on Child Development.

Margaret Kuenne Harlow died on August 11, 1971, following a 4-year battle with breast cancer. Even in death, her career was overshadowed by her famous husband, as her obituary in the *Madison Capital Times* newspaper (August 12, 1971, p. 35) carried the title, “Mrs. Harry Harlow Dies”! However, the Wisconsin newspaper continued with the apt subtitle describing her as a “Noted Primate Psychologist.” The obituary further indicated that “. . . in 1968 [Harlow and Harlow] were jointly awarded National Medals of Science. The award was given for 10 years of research into the love relationships of primates.”

In actuality, the National Medal of Science was awarded only to Harry Harlow, but the newspaper story was not wrong about Margaret Harlow's importance to the work, and about the "love relationship" that she had with the fellow primate that she married and with whom she collaborated for 25 years.

## Mark Test, The

Fanny-Linn H. Kraft  
Centre for Integrative Ecology, Deakin  
University, Geelong, VIC, Australia

## Synonyms

[The mark-mirror test](#); [The mirror test](#)

## Definition

**A method for testing whether an individual is capable of mirror self-recognition (MSR).**

Self-awareness is a cognitive trait that has fascinated philosophers and psychologists throughout history (Keenan et al. 2004). Self-aware individuals are cognizant of their own actions and how they may affect the world around them, and this trait is closely associated with consciousness and theory of mind (Gallup 1970; Keenan et al. 2004). Self-awareness allows an individual to compare its own situation to the situations of others, making it capable of empathy, gratitude, and pretence (Gallup 1998; Keenan et al. 2004). In spite of the great interest in this trait, there are few nonverbal means for psychologists and behavioral biologists to test self-awareness. Studying self-recognition using *the mark test* has become a popular method for assessing whether an individual is capable of self-awareness. In theory, self-recognition is only possible for self-aware individuals, as the subject needs to be aware of their actions in order to understand that their reflection in a mirror is not another individual (Bekoff and Sherman 2004; Gallup 1998).

The mark test involves the application of a mark on the body of the test subject, in a place

not directly visible to them, such as the face or chest (Gallup 1970; Plotnik et al. 2006; Prior et al. 2011). It was independently invented by Gallup (1970) and Amsterdam (1972) and has become the predominant way of testing the presence or absence of mirror self-recognition (MSR) in nonhuman animals and human children. While there are similarities between Amsterdam's and Gallup's methods, the Amsterdam method is more widely used in the field of developmental psychology to test individual development of human infants (Mitchell 1993), and Gallup's method is commonly used by behavioral biologists in studies on nonhuman animals and comparative studies on the species level (Mitchell 1993). When applying the mark, it is recommended that the subject is not aware of the application taking place. In nonhuman animals, this is sometimes achieved by using anesthesia while applying the mark (Gallup 1970, 1998). In children, the mark is applied by a parent rubbing a spot of rouge (hence the test sometimes being referred to as "the rouge test") on the side of the nose of the child (Amsterdam 1972).

After the mark has been placed, the subject is allowed to interact with a mirror (Prior et al. 2011). If the introduction of the mirror results in the subject inspecting or trying to remove the mark, this is considered evidence that the subject is capable of MSR (Prior et al. 2011). Self-directed behavior, such as grooming and inspection of the individual's own body, can also be considered an indicator of MSR (Gallup 1970). Both of these behaviors display that the subject has identified its own reflection and can use the information in the mirror to examine its own body (Gallup 1970; Prior et al. 2011).

All nonhuman animals require training with a mirror before they can pass the mark test (Gallup 1970, 1998; Shettleworth 2010). Initially, most animals behave socially (aggressively or otherwise) towards the reflection (Gallup 1970, 1998; Shettleworth 2010). However, after some time, the animal may begin to inspect the reflection more closely and perform self-directed behavior (Gallup 1998; Prior et al. 2011).

There are some key differences between the Amsterdam and Gallup tests. Firstly, the subjects in the Amsterdam experiments have a parent present during the test. The parent pretends to wipe the infant's nose in order to apply the mark and may ask "who's that?" while looking at the mirror, thus guiding the child towards inspecting the reflection (Amsterdam 1972; Mitchell 1993). The subjects in Gallup's experiment are isolated from conspecifics during the test in order to motivate mirror exploration and are sometimes sedated when the mark is applied (Gallup 1970). Secondly, the two methodologies differ in their interpretation of the subject's behavior. Gallup's method only considers changes in social behavior, self-directed behavior, and time looking at the mirror image as indications of MSR (Gallup 1970; Prior et al. 2011). According to Amsterdam's methodology, infants saying their own names or "nose" are also considered as touching the mark and indicate self-recognition (Amsterdam 1972).

In addition to methodology, there are differences in how the mark test is used between developmental psychology and behavior biology. In developmental psychology, MSR is seen as one of several milestones towards true self-consciousness (Zahavi et al. 2004). The mark test is, therefore, used to examine the mental development of young children, alongside tests that indicate the presence of other aspects of self-awareness (Zahavi et al. 2004). Traditionally, MSR has been used in behavioral biology to test the presence or absence of the MSR trait in species or populations and not to place individuals on a continuous scale of self-consciousness (Bekoff and Sherman 2004; Mitchell 1993).

However, some behavioral biologists consider MSR as one point on a continuous spectrum of self-consciousness (Bekoff and Sherman 2004). The biologists do not use the mark test to assess self-awareness as a dichotomous trait, but rather to interpret MSR as one of several traits that could indicate that the animal has some form of self-consciousness (Bekoff and Sherman 2004; Shettleworth 2010). Although there are inconsistencies in how the mark test is used, the method is still an important tool to investigate

self-awareness in both developmental psychology and behavioral biology today (Plotnik et al. 2006; Prior et al. 2011).

## Marsupial Cognition

Orlin S. Todorov  
School of Biological Sciences,  
The University of Queensland,  
St. Lucia, QLD, Australia

## Introduction

Marsupials are all the members of the infraclass Marsupialia which diverged from the main radiation of placental mammals around 130–160 mya. They exhibit a myriad of adaptations to different habitats, wide array of diet, locomotor modes, and social and mating systems. Even though their point of origin is contested, the earliest metatherian fossil record (comprising marsupials and their closest fossil relatives) has been discovered in Asia and dated to the Early Cretaceous (stretching from 146 Ma and 100 Ma). The earliest common ancestor of eutherians (modern placentals) and metatherians is thought to be *Juramaia sinensis*. Dated back to the Jurassic (160 Ma) and discovered in China, it exhibits scansorial (adapted for climbing) forelimb anatomy, weights around 15–17 g, and based on tooth morphology, was an insectivore. It is more closely related to most modern day placentals than all metatherians including the earliest known *Sinodelphys* and *Deltatheridium*.

All extant marsupials are native to Australia, New Guinea, and the Americas, but the fossil record shows that they have been present on all continents at different points in time. Over 330 extant species of marsupials had been described, with around 100 in the Americas and the rest in Australia and New Guinea.

The main difference between placentals and marsupials regarding cognition can be expected due to difference in their developmental mode (the specific type of developmental stages and conditions that an organism undergoes). Despite their name and designation, the marsupial infraclass does undergo placentation but it is relatively short, and some marsupials do not even have a pouch (marsupium), like the short-tailed opossum

## Marriage

- [Consort](#)

(*Monodelphis domestica*). Besides the confusing naming nomenclature, most marsupials do have a very different developmental mode to placentals. They have very short gestation periods (typically between 2 and 5 weeks) and most of the fetal development takes place in the marsupium. This exposes both the developing offspring and the mother to an array of very different developmental/parental conditions as compared to placentals. This also predisposes differences in cognitive and behavioral development.

The striking difference in developmental mode and early phylogenetic divergence, and the subsequent morphological convergence between the two infraclasses of mammals presents a wonderful opportunity for studies on comparative/convergent cognitive evolution. Despite that marsupials are remarkably understudied from psychological perspective. There are only a handful of studies assessing the cognitive abilities of the infraclass, either purely descriptive or in comparative perspective.

What follows is a summary of the current state of understanding of marsupial cognition, starting off by defining cognition and its neuroanatomical correlates. Some differences in neuroanatomy which might be underlying further differences in behavior and cognition between placentals and marsupials are described, followed by a review of the current literature – starting from the initial interest in marsupial behavior and cognition in the beginning of the twentieth century and summarizing the current state of research on different aspects of cognition – perception, learning, memory, attention, decision-making, and executive functions (flexibility, categorization, problem-solving).

## What Is Cognition?

*Cognition encompasses the abilities of an organism to decode, encode, store and process information from the environment (endogenous and exogenous) in (almost) real time.* This usually results in adaptive or flexible behaviors that maximize the species' fitness. These abilities had emerged and evolved as an assembly of different

properties of the nervous system in combination with other receptive and perceptive systems multiple times in evolution.

## On Neuroanatomical Differences with Placentals

Placentals and marsupials show surprising convergence in neuroanatomy (Karlen and Krubitzer 2007). One major difference is the fact that while all marsupials are relatively lissencephalic (exhibiting smooth cortical surface), placentals do exhibit gyrencephaly (folded cortical surface) more often. It is not clear whether the last common ancestor had a gyrated or smooth cortex, but a case has been made that proposes a secondary loss of gyrencephaly in mammals. If so, this might be an example of secondary loss, that is, lissencephaly might be a derived trait in marsupials and not an indication of “primitiveness” (Kelava et al. 2013).

One notable aspect of marsupial neuroanatomy which sets them apart from placentals is that they lack corpus callosum (Suárez et al. 2018). Most connections between the hemispheres are initiated through the hippocampal tracts or the anterior commissure (diprotodont marsupials, such as kangaroos and koalas have an additional axonal tract called *fasciculus aberrans*), which is more typical of reptiles and birds.

Besides these two significant neuroanatomical differences there is a striking convergence between placentals and marsupials in neuroanatomy, morphology, and behavior in species occupying similar habitats. This indicates a possible set of constraints or limits to the developmental bias on the evolution of the nervous system, resulting in similar solutions to similar pressures of the environment.

## On Perception

### Vision

Visual acuity in marsupials is quite poor compared to more derived placental mammals. This is mostly explained due to their nocturnal or

crepuscular activity pattern which relies more on sensitivity to UV instead of resolution or color vision (Arrese et al. 2006).

Until recently, all marsupials were thought to have dichromatic vision (possessing only two types of cones). Recently, it has been discovered that there are many trichromatic species (i.e., fat-tailed dunnart, honey possum, quenda, and quokka, among others), but up until now it has been impossible to identify the third cone's photopigment unambiguously. The observation that around 20% of the photopigments in the retina of the fat-tailed dunnart (*Sminthopsis crassicaudata*) do not react to short or middle wave opsins has been backed up with behavioral experiments (Arrese et al. 2006). Previously thought to be unique to primates, the third class of cones allow for red–green color discrimination. Interestingly, trichromacy in marsupials is not linked to the X-chromosome, and all cones express a type of rod opsin.

The evolution of trichromacy in marsupials presents an interesting case, where this trait might have evolved at least twice in the infraclass (in polyprotodonts and diprotodonts) if it is assumed that the ancestral marsupial was dichromatic. The explanation as to what might the evolutionary pressures behind that be is challenging – for example, species from similar habitats were shown to have different visual ability. Wallabies have been shown to be dichromats while quokkas trichromats. Further research is needed in order to establish the exact evolutionary pressures behind that phenomenon.

### Audition and Vocalization

Marsupials use vocalization, mostly directed to conspecifics during mating, agonistic territorial encounters, and mother–young interactions (Aitkin 1998). The size and habitat of different species appears to drastically affect calls. Vocal communication seems to be more important and thus more developed in arboreal species (Aitkin 1998). For example, opossums' calls cover very broad spectra (0.5–8 kHz – growl; 1–16 kHz – screech), while dasyurids' calls are usually in the spectral frequencies below 3 kHz. In contrast, the arboreal striped possum's call (*Dactylopsila*

*trivirgata*) has a tonal peak at 2.5 and 5.5 kHz. There is evidence that some small, terrestrial carnivorous species can use ultrasonic frequencies, but most such calls lack harmonic structure. Brushtail possums' (*Trichosurus vulpecula*) hearing sensitivity increases from 2 to 15 kHz, and they could still hear tones between 20 and 35 kHz. The hearing range in northern quolls (*Dasyurus hallucatus*) has been shown to lie between 8 and 10 kHz, while the best frequency of hearing in the American opossum (*Didelphis virginiana*) was shown to be between 16 and 32 kHz which is much higher compared to the quoll.

Low-frequency hearing and calls are related to recognition of conspecifics, mid-frequency ranges are related to interactions with pouch-young, while upper ranges are mainly used during predator–prey encounters (Aitkin et al. 1994).

Finally, similarly to placental mammals, there seems to be broad diversity of spectral sensitivity in different species of marsupials, corresponding to wide array of vocalization frequencies. This probably reflects the variety of adaptations to habitats that these species occupy. These findings strengthen the argument that auditory perception and production are as diverse in marsupials as they are in placentals, reflecting their ability to perceive, process, and react to complex stimuli in the environment.

### Olfaction

Similarly to placentals, marsupials possess main and vomeronasal olfactory system, where the later exhibits pronounced sexual dimorphism in some species, and high structural conservation (Aland et al. 2016). The structure and development of the vomeronasal organ in marsupials indicates that, as in other mammals, the importance of pheromones in reproduction is crucial. This might be especially important for some small dasyurid species, as females from these species are monestrous (only a single estrus in a lifetime) while males are semelparous (sudden death of all males after one reproductive season). Thus, the cost of reproduction in such species is extremely high, and an evolved ability to correctly assess a potential

mate should necessarily rely on highly developed olfactory perception for recognition.

In regards to olfactory cognition, there are no studies up to date addressing questions related to olfactory memory, attention, or categorization in marsupials, despite it being a popular topic of research in other mammals (Zucco et al. 2014).

## Cognition in Marsupials

In lieu of the fact that most extant marsupials can be found in Australia and New Guinea, one of the most studied species of marsupial in the psychological literature is the common opossum (*Didelphis marsupialis*). Most marsupials are understudied in terms of cognition and behavior and little progress has been made in this area of inquiry since a series of pioneering attempts in the 70s (Kirkby 2015). Before that, it was popularly held that marsupials were a primitive mammalian radiation, representing an intermediate form between sophisticated eutherians and primitive reptiles. Even though that notion is no longer supported, almost no advance has been made in the field of marsupial cognition, and the view that marsupials are somewhat primitive is still widely and wrongly accepted.

## Exploration and Problem-Solving

Platt and James (1967) were able to show that adult opossums exhibited preference for novelty, by training them in T or Y mazes with different colors of the different arms. When both arms were changed to congruent color choice, most opossums showed tendency to explore the arm that had changed color. In a larger comparative study Russell and Pearce (1971) exposed 30 animals from 6 different marsupial species to a set of four novel objects with different odor, shape, and texture. Their findings showed similar response to novelty to placental mammals, where repeated exposure led to habituation, with some species showing higher level of reactivity (brush-tailed marsupial rat – *Dasyuroides byrnie*) while others had very quick habituation (i.e., red

kangaroo, *Macropus rufus*, or the Tammar wallaby, *Macropus eugenii*). Other studies had also pointed to similarity in exploration toward novelty between mammals and marsupials (Kirkby 2015) with the little differences been attributed mainly to differences in habitats and diets.

One striking example of problem solving, where possums outperform even primates involves retrieval of a food reward tied to string when the only solution to the task requires the animal to face away from the goal object (Wynne and McLean 1999). In terms of spatial learning, marsupials, and especially opossums, have been shown to be especially apt. On specific maze tasks they seem to perform better than rats, chickens, and even dogs. In rare study in wild animals (Morrant and Petit 2012) the nectar feeding western pygmy possum (*Cercartetus concinnus*) were shown to exhibit very complex exploratory behavior in their natural environment, combined with diet-switching in order to cope with fluctuation in resource availability. Pygmy possums have been detected to travel up to 4.7 km in a single night in search of flowering plants, and when certain food sources were unavailable, they could identify alternative flowering plants to feed on.

## Conditioning and Learning

Attempts for classical conditioning in marsupials had been more controversial in their outcomes. Initially, researchers could not successfully train animals to respond to conditioned stimuli but recent attempts have shown that this is possible, concluding that a suitable choice of stimuli is crucial for conditioning in marsupials (Papini 2005). On the other hand, several species of marsupials had been shown to react very similarly to placentals in regards to acquiring both positive and negative operant responses (Angermeier et al. 1987; Powell and Doolittle 1971). Red opossums (*Lutreolina crassicaudata*) were even shown to acquire similar preference to a box with sugar solution versus an empty box, after only a few daily training trials (Papini et al. 1987).

This was not the case in Virginia opossums, which exhibited better performance with more trials per session (Friedman and Marshall 1965), indicating variation in context learning in marsupials.

In another study (Bonney and Wynne 2004) both herbivorous quokkas (*Setonix brachyurus*) and carnivorous fat-tailed dunnarts (*Sminthopsis crassicaudata*) showed impressive cognitive flexibility. Both species were successful in learning discriminations, learning sets and reversal sets. Dunnarts showed exceptionally fast learning abilities successfully learning reversal sets in one trial, and were the only species which succeeded in transverse patterning tasks (in which each stimulus has a different property contingent on other stimuli with which it is presented) and negative patterning tasks (tasks in which an animal is conditioned to respond to one of two stimuli, but not to the simulations presentation of both). This difference between the two species might be due to the better developed cortical association areas in dunnarts as compared to quokkas.

Such findings lead to the conclusion that operant learning ability does not appear to have evolved after the split between eutherians and metatherians, and that more encephalized animals do not show improvement as compared to less encephalized ones. This might be related to the fact that experimental operant and classical conditioning mostly rely on food as reward. It is a very basic stimulus related to survival, that even the most basic vertebrates should be capable of efficient conditioning to.

## Lateralization

Lateralization of behavior (preferential usage of one side of the body during execution of certain repertoires like extracting fruit, offspring care, etc.) has been shown to be a property of most bilaterally symmetrical vertebrates. It has many implications for behavior and cognition and has been suggested to be a result of an evolutionary stable strategy under social pressures, where asymmetrical organisms need to coordinate their

behavior with other conspecifics or other species (Vallortigara and Rogers 2005).

In a study on southern hairy-nosed wombats (*Lasiorhinus latifrons*) right auditory bias was detected when the animals were presented with eight sounds from different contexts (Descovich et al. 2013). Interestingly, once used to the sounds, the animals reversed their bias to the left side. This is in concert with other studies, indicating that most vertebrates exhibit left hemisphere/right sensory bias for vigilance (Vallortigara and Rogers 2005) and right hemisphere/left sensory bias for familiar objects (Robins and Phillips 2010).

Strong manual lateralization had also been shown to be present in some bipedal marsupials both on individual and on population level (Giljov et al. 2017). Left-limb preference was observed in several species of macropods, and it was shown to be present from the pouch-young stage. These findings suggest that manual preference and lateralization in this group is not determined by habitual bipedality, but it is a result of developmental processes precluding postural and locomotor bipedality. This is in stark difference to most studied placental mammals, where manual lateralization usually manifests with advancing age, with the one exception in primates, where the scenario resembles marsupial's early development. In that sense, both humans and macropods manifest handedness before the adult stage which becomes evident before the development of bipedality.

## Avoidance Learning and Generalization

Predator avoidance in marsupials is one of the best studied areas of cognitive ability in that group with all observations and experiments suggesting that learning processes in marsupials might be convergent with those in placentals. One of the largest members of the Macropodoids, the eastern grey kangaroo (*Macropus giganteus*) was shown to flee if there are dingos or farm dogs in proximity. The fear response toward the farm dogs had also been shown to generalize toward the vehicle the dog always appears around (Jarman and Wright 1993). Several other marsupial species

had been shown to successfully learn to recognize introduced predators. Rufous hare-wallabies (*Lagorchestes hirsutus*) could learn to recognize a stuffed model of a fox and a cat, and quokkas (*Setonix brachyurus*) had been shown to be able to generalize their fear toward dogs to a stuffed model of a cat (McLean et al. 2000). Tamar wallabies (*Macropus eugenii*) were shown to become fearful of a model fox then generalize the response to a cat, but not to a non-predator (goat) (Griffin et al. 2002). The authors interpret this finding as an adaptive predisposition to acquire a fear of predators, based on their subsequent experiments with an array of control stimuli.

### Social Cognition and Play

Tammar wallabies (*Macropus eugenii*), a highly gregarious and social species, can socially transmit knowledge on avoiding a predator model (fox) and can generalize between contexts (Griffin and Evans 2003) – they subsequently avoid cats, but not goats. This was the first instance where social learning was demonstrated in a marsupial species. Another study (Cordonni and Norscia 2014) demonstrated that in the red-necked wallaby (*Macropus rufogriseus*) reconciliation was not only present, but it was also modulated depending on the intensity of the conflict. While low intensity conflicts were reconciled, high intensity ones were not. These findings indicate that the red-necked wallaby can evaluate the costs of conflict and reconciliation and can engage actively in peace-making in an attempt to maximize the pay-offs.

Play has been considered one of the indicators of complex cognition in mammals and birds (Iwaniuk et al. 2001). Despite the scarcity of data, a survey of play behavior among marsupials revealed that play was common in larger-bodied members of Dasyuridae, in *Myrmecobiius*, in Vombatidae, and in all Macropodoidea (Watson 2009). They exhibit a diverse range of social (play fighting, sexual play, and parallel locomotion), nonsocial (locomotor or object play), and inter-specific play. It was shown that the presence of play was related to relative brain mass, but a point

was also made that there might be a confusion in classification of play fight versus real fight, for example in macropodoids (Watson 2009). Some ritualized behaviors in fights categorized as real ones, might have been indicators of play fight instead.

The evolution of play in marsupials, and macropods more specifically, has been analyzed from the scope of their specific social system. Most of the playing macropodoids are polygynous, which necessitates a certain level of competition between both males and females, which can be “rehearsed” while playing. Another contributing factor might have been predation pressure, as macropodoids have been preyed upon by a range of mammals, avians, and reptilian predators throughout their evolution. Training different predator avoidance strategies through locomotor play might be an adaptation alternative to crypsis in some non-playing species (e.g., potoroids).

### Conclusion

The area of marsupial cognition is remarkably underexplored, and despite many potential species that can be studied as model animals the infraclass remains poorly understudied. For example, in species that show evidence of enhanced learning abilities and cognitive flexibility, studying pouch young in their early development provides a great opportunity for research on development and evolution of cognitive abilities. Many species had never been studied in terms of cognition, and there is a substantial gap in our knowledge of memory, cognitive flexibility, social learning, innovation or most types of complex cognition in the group, such as emotions, moral judgment, prospection and planning, theory of mind, and consciousness. Metatherians in general provide a wonderful study system for research on convergence in cognitive ability, and given their differences and similarities in neuroanatomy, they deserve more attention from scholars interested in evolutionary comparative studies, such as neuroecology and cognitive ethology.

## Marsupial Diet

Marianne Sarah Freeman

[Feeding behavior](#); [Metatherian](#); [Nutrition](#)

## Introduction

The marsupials are a varied and diverse group of mammals, with specialized dentition and digestive physiology for each specific niche they occupy. Their dietary strategies include carnivores, insectivores, nectarivores, omnivores (of varying degrees), folivores, frugivores, fungivores, browsers, and grazers. Marsupials have a basal metabolic rate that is about 30% below eutherian mammals. Though, McNab (1978) challenged whether this is due solely to phylogeny or just life history in general, as frugivory and folivory are also associated with

sedentary arboreal habits in both mammal groups. However, this strategy is commonly encountered across the marsupials and can be possibly explained by a survival strategy to overcome the unpredictable environments across their range. Withers et al. (2006) noted that species from arid and unpredictable environments, generally, have lower metabolic rates. Hume (1999) compiled a detailed account of the marsupial diet, nutrition, and physiology. Here the diets and foraging behaviors have been summarized and more recent findings included as well as a consideration of how we can use these diet choices to better understand the cognition of some of the marsupials.

## Diet Strategies

The marsupials can be classed into two groups the Australasian marsupials and the American marsupials. Carnivores of the former have a simple digestive tract with no caecum, whereas a caecum is present in the latter suggesting a more omnivorous diet, although several of these species have a much greater proportion of animal matter in their diet and a dentition that can allow them to be considered as carnivores (Hume 1999).

## Dasyuromorphia

The order Dasyuromorphia includes the family Myrmecobiidae, with the sole species the numbat (*Myrmecobius fasciatus*) and the family Dasyuridae, which ranges from the small planigales to the large Tasmanian devils. The numbats feed principally on termites, scratched from the top soil layers of the forest floor, and scooped up with their long tongue (Cooper and Withers 2004).

The dasyurids have a primitive dentition and a simple digestive system with a rapid passage rate, indicative of typical carnivores with no caecum. The prey choice correlates with body size, whereby the smaller members eat small invertebrates, but larger species can predate on vertebrates too (Hume 1999). The largest carnivorous marsupial the Tasmanian devil (*Sarcophilus harrisii*) is a generalist predator, taking animals ranging from small invertebrates up to large

vertebrates such as seabirds, wallabies, or wombats, which they will either ambush or chase over short distances to catch prey (Jones 2003). They also scavenge on the carcass of wallabies, wombats, quolls, or livestock. The spotted-tailed quoll (*Dasyurus maculatus*) consumes medium-sized mammals and, being particularly good climbers, are well placed to prey on arboreal species such as gliders. They will also supplement this diet with rabbits other medium-sized marsupials as well as some invertebrates and a little plant material (Glen and Dickman 2008). Whisker-like vibrissae on their paws allow them to reach into the dens of their prey, and they can stalk their prey, catching and holding them down with their front paws and will also scavenge on the carcasses of larger animals (Jones et al. 2001). Several of the small to medium-sized dasyurids weighing 6–1000 g can use daily or short-term torpor to help combat food shortages in an unpredictable environment (Munn et al. 2010). Though Pavey et al. (2009) found that the high energetic content of vertebrate prey allows for less frequent and shorter torpor duration. This torpor behavior is also observed in other carnivorous/insectivorous Australian marsupials such as the numbats and marsupial moles.

### Notoryctemorphia

Due to their elusive subterranean and solitary nature, there is very little information on the diet and feeding behavior of the marsupial moles. There are two extant species the southern marsupial mole (*Notoryctes typhlops*) and the northern marsupial mole (*Notoryctes caurinus*). Living in the sandy deserts of Australia, they tunnel rapidly into the sand with their forelimbs and fill in the space behind them with their hind limbs (Pavey et al. 2012). They have been observed in captivity to use their protrusible tongue to lick larvae and eggs of invertebrates from the ground surface, and it is thought that they have a similar feeding behavior underground (Benshemesh and Johnson 2003). A well-developed olfactory sense is likely to allow the moles to locate social invertebrate nests (Benshemesh and Johnson 2003). Museum samples offer an insight into their diet, finding that marsupial moles not only consume social insects

but that beetle larvae are also an important food source (Pavey et al. 2012).

### Microbiotheria

More closely related to Australian marsupials Microbiotheriidae is the only neotropical marsupial family in the superorder Australidelphia. Only one species remains living, *Dromiciops gliroides*, which occupies arboreal forests in Chile. It is primarily insectivorous with a diet of predominately arthropods and insect larvae (Vieira and Moraes 2003). In particular, insects are thought to be important energy sources when they emerge after hibernation (Amico et al. 2009). Though crests on their molars are indicative of an insectivorous diet, their broad molars and flat incisors are more representative of a frugivorous diet (Amico et al. 2009). They are well adapted for climbing (Vieira and Moraes 2003) allowing them to consume fruit to supplement their diet throughout the summer and most probably in the spring, and thus the species is an important seed disperser of mistletoe and other shrubs and trees in Chile (Amico et al. 2009).

### Paucituberculata

The family Caenolestidae are shrew-like insectivores that feed on a variety of animal material from invertebrates to frogs and dead rodents (Martin and González-Chávez 2016). They possess peculiar lip flaps that are thought to prevent their sensory vibrissae and fur being clogged with blood and dirt (Hume 1999). Their dentition is made up of well-developed lower incisors that protrude to the front. Captive animals were noted to stab their prey with these teeth (Vieira and Moraes 2003). Dusk shrew opossum (*Caenolestes fuliginosus*) can climb and jump well using a prehensile tail for balance. No intra-specific aggression in the captive group was observed, and group huddling and non-agonistic feeding bouts were noted suggesting they are not exclusively solitary animals in the wild (Martin and González-Chávez 2016).

### Didelphimorphia

The extent of carnivory in the neotropical marsupials and in the Didelphidae family, specifically,

varies with arboreal lifestyle in that the more arboreal the species is, the less carnivorous the diet that it follows (Vieira and Moraes 2003). This is a large order of marsupials with over 60 small- to medium-sized species. The Patagonian (*Lestodelphys halli*), lutrine (*Lutreolina crassicaudata*), and water opossum (*Chironectes minimus*), which eats crustaceans, fish, and amphibians, are the most carnivorous of the didelphids. Patagonian opossum dentition suggests a carnivorous diet, having very long canines and molars. Apart from the more carnivorous Didelphidae, the rest of the family are omnivores. The Brazilian gracile opossum (*Gracilinanus microtarsus*) opportunistically feeds on both plant and invertebrates, though its diet is primarily made up of insects (Martins et al. 2006). Much work has been carried out on the Virginia opossum (*Didelphis virginiana*), whose dietary range has, in part, allowed them to successfully expand their range across North America (Hume 1999). The species can survive cyclical food availability and low winter temperatures by reducing activity, sheltering in dens, and using up fat reserves, which can result in body weights falling by 27% (Gardner 1982). They have been known to predate on rattlesnakes and show immunity to their toxins. Woolly opossum (*Caluromys* sp.) and bushy-tailed opossum (*Glironia venusta*) and black-shouldered opossum (*Caluromysiops irrupta*) are the least carnivorous of the Didelphidae family.

### Peramelemorphia

The order Peramelemorphia is indicative of the main omnivorous marsupials, comprising of bandicoots and bilbies. Bandicoots are too small to be fully herbivorous and too big to be a generalist insectivore so the omnivorous strategy has been adopted. The diets of all the species vary but include invertebrates, plant material, and fungi (Hume 1999). The greater bilby (*Macrotis lagotis*) is a small omnivorous marsupial with a diet that mainly comprises of beetles, termites, and ants. They show digestive flexibility being able to adapt to seasonal variation, in the cooler months' roots and seeds are also consumed (Navnith et al. 2009). They can dig through the soil to get their food and possess very long

tongues to reach their prey. They have relatively low basal metabolic rate and a low requirement for nitrogen which helps them to adapt to changes in an unpredictable arid environment (Hume 1999).

### Diprotodontia

#### Petauridae

Though some species of the Petauridae can be considered herbivores, many consume a mixed diet that includes invertebrates. This superfamily includes the ring-tailed possum, gliders, and honey possums.

The striped possum (*Dactylopsila trivirgata*) and sugar glider (*Petaurus breviceps*) both have a long fourth digit to pull out insects from bark and enlarged incisors to chew bark and reveal sap. The sugar glider diet varies geographically and seasonally, in summer they eat pollen and nectar from *Eucalyptus* trees and in autumn they change to arthropods (Dobson et al. 2005). Yellow-bellied gliders are the largest glider species; they are exudivores that live socially with vocal communication to help maintain large home ranges. Eucalypt sap is important in the diet of yellow bellied glider (*Petaurus australis*), and they will make a notch in the tree to extract the sap. The Leadbeater's possum (*Gymnobelideus leadbeateri*) is also an exudivore; they are very rare and only found in one specific area of Australia. It is thought that they have microbes in the digestive system to help break down the polysaccharides in the gum. Eucalypt nectar is important to squirrel gliders (*Petaurus norfolcensis*) (Hume 1999).

Reduced dentition and a specialized tongue have allowed the honey possum (*Tarsipes rostratus*) to become unique nonflying pollen and nectar consumers (Bradshaw and Bradshaw 2012). They do not have a caecum and instead digest pollen in the intestines; their stomach is bilobed with a well-defined diverticulum (Bradshaw and Bradshaw 2012).

Encephalization quotas were compared across marsupials and found the honey possums as well as some of the gliders to have an encephalization quota similar to prosimians, suggesting spatial

memory is important for their arboreal lifestyle and dietary requirements (Ashwell 2008).

The rock ringtail possum of the Pseudocheiridae has a mixed diet of fruit, flowers, and leaves; their digestive tract has a small caecum (Hume 1999).

Of the more folivorous species, common ring-tailed possums (*Pseudocheirus peregrinus*) consume the leaves, shoots, and flowers of *Eucalyptus* and other available trees. The green ringtail possum is also highly folivorous, in particular, feeding on *Ficus* leaves. They possess a very large caecum with hindgut fermentation to help digest the high quantity of leaf material. The New Guinean ring-tailed possums are smaller and therefore adapted to a more mixed diet, but all still possessed a large caecum and are thought to be chiefly folivores (Hume 1999).

The greater glider relies almost solely on *Eucalyptus* foliage. Due to this low-quality food resource, it has adapted with shearing teeth to break the leaves into small particles to allow better fermentation in their enlarged caecum. They also have a very low reproductive rate.

#### Phalangeridae

The pygmy possums from the family Burramyidae are more closely related to the *Phalangeridae* family and are included together in the superfamily Phalangeridae. The mountain pygmy possum (*Burramys parvus*) eats moths as well as alpine fruits; the other pygmy possums (*Cercartetus* sp.) primarily consume nectar and pollen but will also eat arthropods and small vertebrates.

The Phalangeridae family are more frugivorous, and the common brushtail possum (*Trichosurus vulpecula*) is a particularly successful species. As with many invasive species, its high fecundity and low reproductive age has allowed it to rapidly establish in new areas. The adaptability it shows to new diets has helped it to maximize resources in new environments. Of the eight New Guinean phalangerids, the ground cuscus is thought to be the most frugivorous, filling the same ecological niche as eutherian sloths and hyrax with extremely low metabolic rate; unlike tree hyrax they spend the day in

burrows or under tree roots and climb tree at night to feed. The dentition is made up of small bunodont molars and very large premolars like other frugivorous mammals (Hume 1999). They have a long small intestine and short caecum, where cell wall digestion takes place. The stomach is unilocular and so can stretch to accommodate large food items (Hume 1999).

#### Hypsiprymnodontidae

The rainforest dwelling, musky rat kangaroo (*Hypsiprymnodon moschatus*), formerly classed within the Potoroidae, has more recently been placed with the extinct rat kangaroos (Burnett et al. 2016). It is now the sole surviving species within the family. Unlike other Macropodiformes it has a simple stomach suited to a lower fiber diet (Hume 1999). They are primarily frugivores eating the fruits and seeds of a large number of plant species and preferring large, fleshy fruits with soft seeds (Dennis 2002). They will also eat fungi when in season (Arman and Prideaux 2015).

#### Potoroidae

The family Potoroidae have been classed as herbivores, omnivores, and fungivores. Bennett and Baxter (1989) observed long-nosed potoroos (*Potorous tridactylus*) to have a seasonal diet variation feeding in the autumn on fungi and seeds and in spring on arthropods. They have long claws on their front feet that help to excavate deep rooted fungi, and as there is a high proportion of fungi (>40%) in the diet of all species in this family with the exception of the burrowing bettong (*Bettongia lesueur*), they should be considered as fungivores. The burrowing bettong has adaptations to allow the consumption of tougher food. This thought to be an ancestral trait to cope with their arid habitat (Vernes and Lebel 2011).

The potoroid digestive system comprises of a sacciform stomach, which allows the storage of high energy foods and a small tubiform stomach. Dentition is that of a basal macropod adapted to a low fiber (seed and fungi) diet where the premolars can cope with large food items such as fungi and can be used to open seed cases before their low crowned molars crush the seeds. Potoroids do not need fibrous material, as the small capacity of

their stomach restricts bulky, low energy, fiber intake (Hume 1999). Their fungal dietary intake is also shared with several browsing macropods.

#### Macropodidae

Arman and Prideaux (2015) reassessed the dietary classification of the macropods putting the quokka and the red-necked wallaby as browsers (with more than 70% browse consumption) and pademelons, swamp wallabies, rock wallabies, and the nail-tailed wallaby as mixed feeders. The brush wallabies, hare wallabies, wallaroos, and kangaroos were combined as grazers (with more than 70% grass consumption).

Tree kangaroos (*Dendrolagus* sp.) are strictly folivorous foregut fermentation, browsers consuming the leaves and stems of a wide range of trees and vines (Hume 1999). The quokka (*Setonix brachyurus*) eats leaves and stems of succulent small trees and shrubs that grow in the swamp shrubland habitat (Hayward 2005).

Very little is known about the diet of the New Guinea forest wallabies. This group of five, currently identified, species has a basal dentition similar to the potoroids and given their small size are expected to consume a mixed variety of vegetation and fungi (Vernes and Lebel 2011).

Pademelons and wallabies (with the possible exception of the rock and nail-tailed wallabies) also consume and disperse a wide range of truffle-like fungi. They scrape away leaf litter from the forest floor, with their front feet to reveal shallow fruiting fungi (Vernes and Lebel 2011). Hare wallaby is considered to be a seed specialist grazer (Arman and Prideaux 2015).

As body mass increases, there is an increasing reliance on a larger intake of grass (Arman and Prideaux 2015). This has resulted in a change to their digestive system. Except for the red-legged and red-necked pademelon, which rely more on the sacciform stomach for digestion, the highly folded tubiform forestomach is the largest gastric region which helps to slow the passage of the higher fiber food and thus aid digestion (Hume 1999). In the larger kangaroos, the tubiform region is much larger relative to the sacciform region. Incisors bring food in and rows of uniform large ridged molars are used for cutting and chewing grasses.

#### Vombatidae

Wombats are the largest burrowing mammals, weighing up to 50 kg; this is even more unique when the combination of herbivory is considered. They forage on low nutritional perennial grasses and so have distinct adaptations to extract enough energy from their food source in order to expend the energy and time to dig their burrow. However, once a burrow is created, living underground is an energy-saving strategy, with less need to be alert for predators and the thermoregulatory properties of a burrow help to keep the animal cool in the shade and protected from the cold (Finlayson et al. 2005).

They are the only marsupials to possess continuously growing teeth and as these teeth wear, they are left with sharp cutting edges. The molars are left particularly sharp on the cheek side of the lower jaw and the tongue side of the upper jaw allowing food to be reduced to very small particles and thus facilitating the extraction of higher nutritional content from their diet (Hume 1999). Southern hairy-nosed wombats (*Lasiornhinus latifrons*) feed in halo-like circles from their burrow, obtaining the most nutritionally valuable new shoots as they emerge. Very little is known about the diet of the highly endangered Northern hairy-nosed wombat (*Lasiornhinus krefftii*). Common wombats (*Vombatus ursinus*) are generalist feeders, foraging on any available tussock grasses in the mosaic habitat that they occupy (Evans et al. 2006). The digestive system of both these species reflects the differences in their diet. The Southern hairy-nosed wombats have a relatively large small intestine and small proximal colon, whereas the common wombat has a relatively short small intestine (Hume 1999).

#### Phascolarctidae

Koalas, though arboreal folivores, feeding almost entirely on *Eucalyptus* species, still share many features with wombats, they both have a backward facing pouch and a vestigial tail, a specific gland in the stomach, and a diastema between the incisors and the premolars.

*Eucalyptus* has a low nutritional value and is high in toxins (Hume 1999). Koalas are exposed to gut microbes as joeys, through the feeding of

pap as a mechanism to overcome the toxic substances in the *Eucalyptus*. Koalas need to have large digestive system to cope with enough food in order to get enough energy, but they need to be small enough to be mobile so they have developed physiological and metabolic adaptations (Moore and Foley 2000). They have very low energy requirements, resting for a large proportion of the day. They have a simple stomach and an extremely large caecum and proximal colon where fermentation takes place with specific mechanisms to allow particle separation in the stomach; large particles will pass through and smaller particles are retained in the caecum and proximal colon for further digestion.

Olfactory cues are important for koalas who will often scent mark the base of a tree with urine or sternal gland (in males). Koalas will also sniff the base of a tree before climbing. When selecting leaves, koalas will grasp the branches with their front paws and sniff the leaves before they are stripped and eaten.

Out of the 600 species of *Eucalyptus*, koalas have been recorded using up to 120 different species (Moore and Foley 2000). Their dietary preference varies geographically, and while this is in part due to the geographical variation of tree availability, there has been some evidence of a difference in preference between koala populations. For example, a study in New South Wales found that koalas would eat *Eucalyptus radiata* but that koalas in Victoria actively avoided it even to their own detriment (Moore and Foley 2000).

Koalas and other sympatric folivores have been shown to actively select against high plant secondary metabolites such as tannins and phenolics, especially formylated phloroglucinol compounds (FPC) (Foley et al. 2004). The act of sniffing the leaves before consumption is seen as a method of determining FPC concentrations and that prior learning plays a part too (Moore and Foley 2000). This could be through negative past experiences such as the post ingestive consequences of secondary metabolites of *Eucalyptus*-like FPC's and other substances or pre-ingestive experiences, for example, exposure either in utero, via lactation, by social observation or through pap feeding. Though learning through

foraging consequences or conditioned food aversions has not been seen in koalas; there is evidence for this in common ringtail possum and brushtail possum (Lawler et al. 1999).

## Conclusions

Marsupials, with the exception of the honey possum, have a low basal metabolism, and suggestions have been made that this low metabolic rate results in lower cognitive abilities. Evidence suggests that some marsupials' diets and lifestyles have resulted in encephalization quotients that are equivalent to that of similar-sized eutherians. Many marsupials have evolved unique physiological and cognitive strategies to cope with the challenges that they are faced with, be it unpredictable environments or specialized dietary niches. With such a highly specialized group of animals, it is likely that more will be revealed about how they navigate through their habitat in search of food, choose the best food to maximize their energy intake, or learn to avoid predators. However, with pressure from eutherian invasive species and human disturbance, many of these unique species are under threat. We can only hope that important information about their ecology, behavior, and cognition comes to light before it is too late.

## Marsupial Life History

Alaina Macri  
The Royal Zoological Society of Scotland,  
Edinburgh, UK

### Definition

A marsupial life history refers to the series of changes a species in the marsupialia infraclass undergoes throughout its lifetime. These events include age and stage patterns associated with reproduction, growth, and survival.

### Introduction

Marsupials are part of the mammalian class; however, they are then further categorized into the clade Metatheria and infraclass Marsupialia. The main difference between a marsupial mammal and other mammal species is the manner in which they carry their young. Marsupials will give birth to a very immature fetus, which then crawls up the mother's abdomen to a pouch or pouch-like area where it attaches to a teat, then continues its development. In comparison a placental mammal will undergo much of its development internally in the uterus (Archer and Kirsch 2006).

**Kingdom:** Animalia  
**Phylum:** Chordata  
**Class:** Mammalia  
**Clade:** Metatheria  
**Infraclass:** Marsupialia

There is a wide variety of marsupials, overall there are 7 extant orders, which include over 330 species. Figure 1 depicts the two major

divisions of marsupials which are Ameridelphia (3 orders) and Australidelphia (4 orders), ones found in the Americas and those in Australasia, respectively (Archer and Kirsch 2006).

Marsupial are very diverse in all aspects, and they range in size from the long-tailed planigrade (*Planigrade ingrami*) weighing just 4.5 g to the largest the red kangaroo (*Macropus rufus*) weighing around 90 kg (200 lbs) and can grow to be 2.18 m (7.2 ft) tall (Dickman and Vieira 2006).

They occupy a diversity of terrestrial habitats, but there are no truly aquatic marsupials. There are however two South American species which are closely associated to water, the lutrine, and water opossums. The majority of Ameridelphia marsupials are forest dwelling species. The woolly opossums are arboreal animals preferring tropical forests, whereas the slender mouse opossums dwell more on the forest floor and occasionally intermediate levels. There are some species that are quite adaptable to many habitats and are even found in urban areas, such as the American opossums (*Didelphis spp.*) and the Australian common brushtail possum (*Trichosurus vulpecula*) (Dickman and Vieira 2006).

Marsupials also vary in their activity patterns and diets. Some are entirely nocturnal like the sugar glider (*Petaurus breviceps*), whereas others are diurnal like the numbat (*Myrmecobius fasciatus*). Diet wise they range from specialist herbivores such as the koala (*Phascolarctos cinereus*) to carnivorous species such as eastern quolls (*Dasyurus viverrinus*) and Tasmanian devils (*Sarcophilus harrisii*) (Dickman and Vieira 2006).

The wide variety of niches that they fill has an effect on their various life history strategies. A life history strategy is an adaptive set of traits that has evolved over time that allows a species to maximize their fitness. Throughout this entry, there will be examples of key species that have specific physiological and behavioral adaptations linked to their life history.

### Reproduction

#### Mating

The niche of marsupials play a role in determining the social systems of each species, and this is then

### Marsupial Life History,

**Fig. 1** Phylogenetic tree of marsupials depicting orders in red, genus in black with representative species from selected genus in that group (Nilsson et al. 2010)

connected to their seeking, finding and mating behaviors.

When male and females live solitary lives, it is likely that they will use vocalizations and/or odors to attract a mate (Fig. 2). In American opossum species (didelphids), both sexes emit short clicking sounds prior to physical interactions, *Planigale*, and *Antechinus* females also produce clicks or “tstitts” sounds that the males may then join in with to create a duet (Croft 1982).

In dasyurids like the spotted tail quoll (*Dasyurus maculatus*), females have been known to produce extended “cp-cp” calls during estrus, whereas female common spotted cuscus (*Spilocuscus maculatus*) will emit loud braying calls. Male marsupials such as the fat-tailed dunnarts (*Sminthopsis crassicaudata*), Tasmanian devil (*S. harrisii*), and common brushtail possum (*T. vulpecula*) all make distinctive sounds when pursuing females for mating. Some species also vocalize while intromission is taking place (Croft and Eisenberg 2006).

Research into odor producing glands in marsupial has found that 40 out of the 73 genera have such glands. Marsupials have a large olfactory bulb and a well-developed vomernasal organ suggesting that olfactory communication is an important part of their sexual behavior repertoire (Russell 1985). Further evidence to support the notion that scent is relevant to mating is when males encounter females they will attempt to sniff her cloaca and pouch, urine taste, and flehmen (Coulson 1989).

In many marsupial families, including didelphids, phalangerids, and petaurids, there is a sternal gland which is used for scent marking. In some species, the gland is more prominently seen in the males like with the sugar glider (*Petaurus breviceps*), whereas in koalas the gland is completely absent in the females (Fig. 3) (Croft and Eisenberg 2006). All odor producing glands may not be associated with attracting a mate; however, they are honest

Schouten

signals for potential mates and rivals (Zala et al. 2007).

In marsupials mate competition can be fierce and violent. Populations are generally made up of choosy females and roaming males. Male North American opossum (*D. Virginia*) travel greatly during breeding seasons to find multiple receptive females. When they find one, as many as three other males may be in direct competition with him, disputes are settled through aggression and inter-male dominance. Male to male competition is common among marsupials and not only takes the form of fighting for access to females but mate

guarding as well. In several dasyurids, coitus can be many hours long and he will then stay with the female until her estrous has passed (Croft and Eisenberg 2006).

Although many marsupials are fairly solitary and practice a promiscuous mating system, small groups or even monogamous pairs can occasionally form in petaurids (Fig. 4), macropods, and phalangerids (Russell 1984).

Males can choose monogamy when a female and her range are defendable. In the short-eared possums (*Trichodurus caninus*), the male and female will have exclusive use of a core area that

**Marsupial Life History,**

**Fig. 4** A pair of sugar gliders (*Petaurus breviceps*)

M

will only marginally overlap home ranges of other possums.

Another scenario that can occur is stable female groups can form when female home ranges are not defendable. A male may gain access to a group of females and defend them from other males, in a loose harem style system. This can occur in species such as the Greater bilby (*Macrotis lagotis*) and burrowing bettong (*Bettongia lesueur*).

In the macropods, you will generally have aggregations of individuals in high resource areas, with males forming a hierarchy based on size. Male Eastern grey kangaroo (*M. giganteus*)

may even hold the alpha position for up to 2 years (Croft and Eisenberg 2006).

**Parental Care**

The gestation period in marsupials is very short, just 9–45 days and the young that are born always weigh less than 1% of the mother's body weight (Dickman and Vieira 2006; Mills et al. 2012). When the tiny babies are born, they will have to climb their way to the mother's pouch. In the hopping Macropodidae family, the pouch opens upward so the young have a fair way to climb to get there. In burrowing type species that belong to the family Vombatidae, the pouch opens towards

**Marsupial Life History,**  
**Fig. 5** Female numbat  
 with young. (Photo  
 courtesy of Gary Blagden  
 and Project Numbat)

the rear so it is a shorter journey. The opening position can be directly related to the species locomotor behaviors.

Not all species of marsupial have a fully developed pouch, and members of the numbat family (Myrmecobiidae) do not have a pouch as such, but rather the young are protected by extra hair and swollen skin in the abdomen area. The babies will attach to a teat just like other marsupials and stay attached for up to 6 months (Fig. 5). After which she builds a nest and continues to suckle them until they wean at about 11 months. Other pouchless, nest building marsupials include the kowari (*Dasyuroides byrnei*) who have simple grass nests and the brush tailed phascogale (*P. tapoatafa*) who builds an elaborate nest with bark strips and fibrous materials (Croft and Eisenberg 2006).

In general, body size and lifespan will play a role in determining litter size and weaning age. Larger longer lived animals will have smaller litters (1 joey) and longer weaning times (12 months) as in the Red kangaroo (*Macropus rufus*), whereas species that have relatively short lifespans of just 1 year like the Robinson's mouse opossum (*Marmosa robinsoni*) will have larger litters (10–14 joeys) and shorter weaning times (9–10 weeks). Table 1 draws upon two reviews and additional sources to give examples of a variety of species in connection with their life history traits.

In grazing herbivore species, like the kangaroos that only produce one joey in a litter, it is

possible for them to be caring for and carrying more than one joey at various life stages. One that is out of the pouch yet still nursing, one attached to a teat in the pouch. The two young that are nursing have their designated teats, with each producing the right nutrient level milk with regards to their stage of growth. She may also be carrying a fertilized ovum that remains in embryonic diapause until the oldest joey has weaned (Dickman and Vieira 2006).

In general male marsupials do not play a role in the care and rearing of the joeys. There are a few exceptions to this rule, however, like the male sugar gliders (*P. breviceps*). They will huddle, guard, and even groom their young. So other than the few exceptions, the sole care of marsupial young is the responsibility of the female, she will be the one who nourishes them and protects them from environmental conditions and predators.

In 1982, Russell categorized marsupial maternal care into three types that were determined by the pouch anatomy, the nesting habits, and mobility of the young once they permanently exited the pouch.

Type I strategy is exemplified by the fact these females have rudimentary or are lacking pouches; this category includes mothers of the didelphid, most dasyurids, and myrmecobiids families. Some genera in these families will have a more defined pouch when lactating like the large American opossums (*Didelphis*), monito del monte (*Dromiciops*), and some species of woolly

Marsupial Life History, Table 1 Life-history traits of marsupials categorized by dietary group

| Species                                                   | Mean male mass | Mean female mass | Age of first reproduction (months) | Seasonality of reproduction | Weaning age (weeks) | Bouts of reproduction per year | Interval between litters (days) | Litter Size | Life span                      |
|-----------------------------------------------------------|----------------|------------------|------------------------------------|-----------------------------|---------------------|--------------------------------|---------------------------------|-------------|--------------------------------|
| <b>Carnivores</b>                                         |                |                  |                                    |                             |                     |                                |                                 |             |                                |
| Sandstone antechinus ( <i>Pseudantechinus bilarni</i> )   | 40 g           | 30 g             | 11                                 | Seasonal: short             | 12                  | 1                              | 365                             | 5           | M – 24 months<br>F – 36 months |
| Paucident planigale ( <i>Planigale gilesi</i> )           | 52 g           | 52 g             | 12                                 | Seasonal: long              | 9–10                | 1–2                            | 365                             | 6–8         | < 36 months                    |

| Koala ( <i>Phascolarctos cinereus</i> )                   | 9.2 kg         | 6.5 kg           | 24–36                              | Seasonal: long              | 48–52               | 1                              | 365                             | 1           | 15 years                       |
| Common brush tail possum ( <i>Trichosurus vulpecula</i> ) | 3.5 kg         | 2.5 kg           | 12                                 | Seasonal: long              | 26                  | 1–2                            | 200                             | 1           | 12.5 years                     |
| Quokka ( <i>Setonix brachyurus</i> )                      | 3.6 kg         | 2.9 kg           | 18                                 | Non-seasonal                | 39                  | 1–2                            | 185–365                         | 1           | 5 years                        |
| Eastern grey kangaroo ( <i>Macropus giganteus</i> )       | 50 kg          | 27 kg            | 18                                 | Seasonal: long              | 78                  | 1                              | 362                             | 1           | > 16 years                     |

Table comprised of information from Dickman and Vieira 2006; Jackson 2003; Dooley 2004; Kimble 1997; Phillips et al. 2017; Tyndale-Biscoe and Renfree 1987; Kahn 2005; Menhorst 1995; Jackson et al. n.d.; and Smith, 2004

opossums (*Caluromys*), whereas other genera are completely lacking a pouch regardless of lactation like the mouse opossums (*Marmosa*) and fat-tailed mouse opossums (*Thylamys*). These females will commonly produce large litters that stay in the pouch for only a short amount of time before they are deposited in a nest in a fairly immature state of having eyes closed, little fur, and unable to control their own thermoregulation. It is likely that this strategy has been adapted due to the poor protection from the basic pouch, but also the mass of the growing young would impede upon the mother's foraging and predator evasion (Croft and Eisenberg 2006).

The type II strategy has been adopted by members of the peramelidae, petauridae, and vombatidae families. The abdomen area of these females is completely covered by a flap of skin, with an opening that can be to the anterior, as is the case for some cuscus and brushtail possum (phalangerids) and honey possum (tarspedids), or it can open towards the posterior as it does in bandicoots (peramelids) and wombats (vombatids) (Fig. 6).

Young of these mothers leave the pouch further developed than those of Type I. They will have their eyes open and be fully furred and able to move about in the nest/burrow. There may be a transitional phase where they only stay in the nest area, but full emergence will be classed as when

they go with their mother for the first time. Some will follow behind like bandicoot and some will be carried on the mother's back like in the gliders and possums.

Finally, the type III strategy is seen in the macropodids, potoroids, and phascolarctids families. These females have a well-developed pouch and carry their young for relatively longer periods of time with full emergence and weaning taking place later than type I and II species. At the age of permanent emergence from the pouch, they are a little heavier than equivalent precocial placental mammals at birth (Croft and Eisenberg 2006).

Overall, the young of Type I are emerging from the pouch and being weaned at a greater maternal body mass (MBM) than in type II or III. For example, in the common planigale (*Planigale maculata*) young are left in a nest at about 70% of the MBM, and when the litter reaches weaning age they are 300% of her MBM. Whereas in a type II species such as the Southern hairy nosed wombat (*L. latifrons*) young leave the pouch at approximately 20%MBM, in a type III species like the red kangaroo (*M. rufus*) are weaned at 44% MBM (Croft and Eisenberg 2006).

## Growth

The most amazing adaptation to marsupials is the fact they give birth to such tiny immature young in comparison to placental mammals (Fig. 7).

All marsupial species start off life at less than 1% of that of their mother's body mass and many species are much less than 1%. Eastern grey kangaroo female weigh on average 27 kg and the weight of their joey is approximately 4 g; therefore, her young is 0.01% of her body weight. Comparatively, a North American white tailed deer doe weighs on average 65 kg, and her fawn at birth weighs 3.6 kg, thus having a baby at 5.5% her body weight (Haugen & Davenport, 1950).

As an example of the growth process we will look at the stages of macropodids. After birth, the joeys will spend a long time attached to a teat and developing in the pouch before their first emergence. The next stage will be for permanent

**Marsupial Life History, Fig. 6** Wombat joey in rear facing pouch. (Photo by Tapio Salmel)

**Marsupial Life History,**

**Fig. 7** Cleared-and-stained marsupial (grey short-tailed opossum, *Monodelphis domestica*; left) and placental (four-striped grass mouse, *Rhabdomys pumilio*; right), showing differences in development at time of birth. Bony elements are highlighted in pink. (Image from Goswami et al. 2009)

emergence from the pouch and then weaning and postweaning (Croft and Eisenberg 2006).

For the Eastern grey kangaroo, a chart of progression has been produced to assist in the rehabilitation of joeys that have lost their mothers. In the guide, it states that joeys under 250 g are usually not viable for hand rearing.

A joey that is 250–550 g is less than 4 months old, will still be furless, and have its eyes closed and ears down. By 5 months the ears will come up and the eyes will open. By 6–7 months they will have a fine covering fur and weigh about 1380–1700 g and possibly start poking their heads out of the pouch. At 7–8 months they are fully furred and they will make their first emergence from the pouch at an approximate weight of 1700–2240 g. By the age of 9–10 months they weigh 3.3–5 kg and have no trouble in grazing outside of the pouch during the day. When they reach 5–10 kg, they are about 10–13 months old and are ready for permanent emergence; however, it is advised they will not be fully weaned and ready for release until they are 15–18 months old and in the weight range of 15–20 kg (Dooley 2004).

Once fully grown, many marsupial species show sexual dimorphism with the males being the larger sex. In phascolarctids and dasyurids, the males can outweigh the female by approximately 70% as is the case in of the koala and Eastern quoll (Table 1). Interestingly, the wild growth rate of male and female littermates of *Phascogale tapoatafa* and *Dasyurus geoffroii* is

the same until the young start to forage for themselves, after which the males will increase in size to be greater than that of their female siblings (Soderquist 1995).

## Survival

### Longevity

As depicted in Table 1, you will have seen the marsupial life span varies greatly from the short lived species, like the antechinus to the relatively long lived species like the kangaroo.

Many males in the antechinus species are semelparous, which means they only breed once in their lifetime. For example, the subtropical antechinus reach sexual maturity at about 11 months then die at about 12 months old after an exhausting breeding season where they do little else than mate, females may live long enough to see a second breeding season. Robinson's mouse opossum (*M. robinsoni*) also have a short life span of just 12 months for both sexes; however, the female may be able to deliver two litters in that year.

For most marsupial species, body size does correlate well with lifespan, i.e., the larger the body size the longer the lifespan. One of the exceptions to this rule is in the large American opossums (*Didelphis sp.*). They have an unusually low survivorship given their size (2.3 kg) as less than 20% survive to a second breeding season (Dickman and Vieira 2006).

The Robinson's mouse opossum, antechinus, and the large American opossums are known as R selected organisms, which means they mature and reproduce quickly, produce large litters with low survivorship and have relatively limited parental investment. On the other hand, koalas and kangaroos tend to be more akin to a K-selected species, meaning they have longer lifespans and mature slower, their young have a low mortality rate and higher survival rate, and the parental investment tends to be higher than that of r selected species (Post & Thompson, 2018).

Senescence is the process of aging or physiological deterioration over time. For some marsupials like the antechinus, this happens very quickly and predictably, whereas in others the process can be much slower with more variation. A study into northern brown bandicoot (*Isodon macrourus*) examined the lifespan, weight, and litter sizes of wild bandicoot. They found that lighter females were less fecund in their third reproductive season than heavier females; this result indicated that reproductive senescence had a greater impact on smaller females (Price-Rees et al. 2011).

### Predation

Antipredator behaviors are based on a variety of variables ranging from animal size, to resource distribution to habitat type.

Larger marsupials like the macropodids that occupy open pastures are able to congregate and form groups known as mobs for increased predator detection but also for the affect that central individuals will have a higher chance of escape than periphery ones. In western grey kangaroo (*M. fuliginosus*), the size of the group will correlate with the habitat type; the more open the habitat the larger the group; thus, the groups found in woodland areas will be smaller (Croft and Eisenberg 2006). Larger kangaroo species have few natural predators, today mainly dingos and man however in the past they would have been a main prey source for the thylacine (Figueirido and Janis 2011).

Smaller species who lack the ability to out run a predator will tend to live concealed lives and rely more on avoiding detection. Gumnivore species like the yellow bellied glider (*Petaurus*

**Marsupial Life History, Fig. 8** Virginia opossum in death feigning behavior. (Photo by Bruce MacQueen)

*australis*) live in forests and are exclusively nocturnal as their main food source of plant exudates tend to be found in uncovered areas.

Finally, one of the most famous antipredator behaviors of a marsupial is death feigning. Although many species will freeze on predator detection, few will “play dead,” there are only two known marsupial species to do this: the Virginia and the white-eared opossums. When a serious predator threat arises, the opossum will flop over on its side and assume a position with its tail curved in, eyes open, mouth open, and tongue extended (Fig. 8). It will also urinate and defecate and its heart rate and respiration will go down. When a study was done on the behavior, the dogs used to illicit this response did lose interest when the death feigning behavior occurred (Kimble 1997).

### Conclusions

Although there is an extensive diversity of marsupial species with many varying life history strategies, in regards to growth, survival tactics, and reproduction they do all share some commonalities. They must all seek a mate, give live birth to immature young, and all find a way to survive in their own niche.

The marsupial infraclass and our knowledge of it is expanding all the time; in 2014 two new

species of antechinus were added to the genus (*Antechinus vandycki* and *Antechinus swainsonii mimetes*). These dusky antechinus species were discovered in Tasmania and the Australian eastern mainland, and they too exhibit the extreme life history trait of males mating themselves to exhaustion and death (Baker et al. 2015). We are also still learning new things about the species that we do know exist, as it has just been recently discovered through fossil records that the marsupial moles (*Notoryctes*) of Australia were not originally desert dwelling species as they are today in fact prehistorically they were rainforest species (Archer et al. 2010). So with each new discovery we will be able to build up a bigger picture and greater understanding of the fascinating life histories of marsupials.

## Synonyms

Marsupial gaits; Metatherian locomotion; Pouched mammal locomotion

## Definition

Movement used by pouched animals (e.g., opossums, possums, koalas, kangaroos) to traverse their environment.

Marsupials, also referred to as the metatherians, are classified as mammals that typically carry their young in an abdominal pouch. The pouch (also known as the marsupium) is an external flap of skin that encases the nipples. The pouch is supported by the epipubic bone. Not all marsupials have this external covering. The marsupials differ from most other mammals because they give birth to very underdeveloped young that are still in the embryonic stage. Marsupials tend to spend less time growing in the womb and more time in the pouch. Due to the short gestation period, a placenta is not required to nourish the young. Instead, a large yolk sac is developed to provide nutrients to the embryo for three to seven weeks. Once the embryo enters the pouch, it is nourished through the mammary glands sometimes for nine months depending on the species (Cardillo et al. 2004; Horovitz and Sánchez-Villagra 2003).

There are roughly 300 different species of marsupials, and today are endemic to Australasia and the Americas. Marsupials are endothermic like placental mammals; however, they maintain a slightly lower core body temperature. Some marsupial exemplars include the kangaroos, wombats, koalas, wallabies, opossums, and possums. Australian marsupials can be further categorized with their diet. Dasyurids are meat consuming marsupials. This group includes the Tasmanian devil, dunnart, and mulgara. Peramelemorphs (e.g., bilbies and bandicoots) consume meat and plants. Diprotodonts (e.g., kangaroos, wallabies, and koalas) primarily consume plants (Cardillo et al. 2004). Syndactyly is a curious morphology of the foot found in many marsupials species (Horovitz and Sánchez-Villagra 2003). It is traditionally defined as a condition in which digits II and III of the foot are bound by skin and are reduced. From a locomotor perspective, the marsupials demonstrate a wide range of locomotor modes. This chapter will introduce terrestrial and arboreal locomotion, swimming, and gliding.

## Terrestrial Locomotion

The terrestrial gaits of marsupials can be divided broadly into quadrupedal and bipedal locomotion. The quadrupedal gaits of marsupials are consistent with other mammals. At low speeds, the lateral-sequence diagonal-couplet walk is most common (Fig. 1). This footfall sequence is inherently stable due to the generally low proportion of the stride spent as a unilateral bipod (~22%), and the relatively high proportion of the stride spent as a diagonal bipod (only two contralateral limbs in contact with the support) and large tripod (three widely splayed limbs in contact with the support). In general, foot positions arranged as diagonal bipods and large tripods are thought to be highly stable (Cartmill et al. 2002; Granatosky 2018b). It should be noted that both lateral-sequence lateral-couplet and diagonal-sequence diagonal-couplet gaits (see “[Arboreal Locomotion](#)” section below) are also present in marsupials. At higher speeds, trots (i.e., diagonal limb pairs move together with a slight aerial phase) and half-bounds (an asymmetric gait in which the hind left-right pair are in phase while the fore left-right pair are somewhat out of phase) are common (Pridmore 1992; Santori et al. 2005). Limb-loading is

**Marsupial Locomotion, Fig. 1** Hildebrand plot showing the relationship between hindlimb duty factor (%) and phase (%) for seventeen marsupial species

generally consistent across the quadrupedal marsupials. The forelimb serves a net-braking function and supports a majority of body mass. In contrast, the hindlimb serves to propel the body forward. Both limbs have low mediolateral forces, despite the semi-sprawling postures of many quadrupedal marsupials (Granatosky et al. 2020).

The natural habitats of most small marsupials are filled with heterogeneous substrates, including sloped terrain, rocks, and fallen and growing vegetation. However, most studies of marsupial locomotion have been conducted on flat runways. Lammers et al. (2006) collected data from gray short-tailed opossums (*Monodelphis domestica*) moving along level, inclined, and declined trackways instrumented with a force platform to understand how small terrestrial quadrupeds deal with the challenges of substrate heterogeneity. Patterns on the level terrain were typical for nonprimate quadrupeds: the forelimbs supported most of the body weight, forelimbs were net braking and hindlimbs net propulsive, and both limb pairs exerted small laterally directed impulses. On sloped substrates, *M. domestica* moved more slowly, suggesting a need for cautious locomotion. On inclines, both limb pairs were more protracted at touchdown and more retracted at liftoff, fore- and hind limbs had equal roles in body weight support, and the forelimbs exerted greater propulsive impulse than hind limbs. On declines, only the forelimbs were more protracted at touchdown. Additionally, forelimbs supported the great majority of body weight while they generated nearly all the braking impulse. These findings highlight that terrestrial locomotion is not always as simple as is often portrayed in the literature (see Granatosky 2018a), especially for small animals, and that the marsupials are capable of an impressive level of intrinsic locomotor plasticity in the face of mechanically challenging substrates.

The bipedal gaits of marsupials are most notable in the macropods (i.e., kangaroos and wallabies). The locomotion of a kangaroo is described as a hopping behavior. The two hind limbs are synchronized with each other and the forelimbs do not contact the substrate. The long tail is outstretched behind the animal and serves as a counterbalance. This type of locomotion

exemplifies the ability of the limbs to store and recover energy. At high speeds, kangaroo hopping ranks among the most energy efficient means of terrestrial locomotion. Much of this energy recovery has been attributed to the unusual set of anatomical features observed in the macropods. Tendons and ligaments located in the hind limbs and the tail of kangaroos provides the storage for elastic energy return. Furthermore, when kangaroos speed up, they do not increase the frequency of their hops, but rather stride length. The greater the length, the more energy they harness in their muscles and tendons after they touch down (Kram and Dawson 1998).

While the kangaroos and wallabies are best known for their hopping ability, these grazing animals spend much of their time moving slowly (Kram and Dawson 1998), and when they do so, the tail has an entirely different function. They plant it on the ground in sequence with their front and hind legs in a distinctive gait referred to as “pentapedal” locomotion, with the fifth point of contact being the tail. O'Connor et al. (2014) found that the tail is responsible for as much propulsive force as the front and hind legs combined. It also generates almost exclusively positive mechanical power, performing as much mass-specific mechanical work as does a human leg during walking at the same speed. Kangaroos use their muscular tail to support, propel and power their pentapedal gait just like a leg.

## Arboreal Locomotion

The exploitation of an arboreal environment provides access to diverse resources and minimizes risk from terrestrial predators. However, the diversity of available arboreal substrates (i.e., variable size, inclination, length, fragility, etc.) presents a demanding, discontinuous, and unpredictable three-dimensional environment that imposes important and differing constraints to arboreal marsupials. As such, arboreal marsupials have evolved a range of anatomical and biomechanical adaptations that have allowed them to navigate in trees safely and effectively (Karantanis et al. 2015; Schmitt and Lemelin 2002; Shapiro and Young 2010).

In an arboreal context, gait patterns may serve as a behavioral mechanism to enhance stability and safety (Granatosky et al. 2019). These gaits can be either symmetrical, when the left and right limbs of a pair alternate, or asymmetrical, when the left and right limbs move more synchronously. Diagonal-sequence gaits [hindlimb footfall is followed by a contralateral forelimb footfall (i.e., right hindlimb, right forelimb, left hindlimb, left forelimb)] contribute to dynamic stability in arboreal substrate navigation and reduce the periods of the stride where the limbs are arranged as unilateral bipod. These gait sequences have been observed in Woolly opossums (*Caluromys philander*), feathertail gliders (*Acrobates pygmaeus*), and koalas (*Phascolarctos cinereus*) (Gaschk et al. 2019; Karantanis et al. 2015; Schmitt and Lemelin 2002). In contrast, lateral sequence gaits may be functionally linked to static stability in substrate navigation and maximize the proportion of the stride where the limbs are positioned as a wide polygon of support. This is the strategy used by the sugar glider (*Petaurus breviceps*) (Shapiro and Young 2010). During arboreal locomotion, duty factor usually decreases on larger substrates (i.e., longer swing phase) along with an increase in the frequency of asymmetrical gaits (Granatosky et al. 2019; Karantanis et al. 2017).

Asymmetrical gaits, including gallops, half-bounds, and bounds, are commonly used by arboreal marsupials at high speeds and frequently include a whole-body aerial phase (Granatosky 2018b; Hildebrand 1980). It has been proposed that asymmetrical gaits may be preferable over symmetrical gaits during faster locomotion as they confer a reduction in the peak reaction forces, decrease the strain on the musculoskeletal system, and may optimize metabolic costs, at least at the trot-gallop transition (Hoyt and Taylor 1981). For small arboreal marsupials (e.g., *Dromiciops australis*, *M. domestica*, and *Lutreolina crassicaudata*), asymmetrical gaits further confer advantages in stability by limiting center of mass oscillations (Lammers and Zurcher 2011; Pridmore 1994; Santori et al. 2005).

Beyond categorical gait sequences, arboreal stability is also influenced by speed, which is a

function of stride frequency and stride length (Granatosky et al. 2019; Karantanis et al. 2017). Increased velocity during arboreal locomotion can be achieved either by increasing stride frequency, and decreasing stride length, by increasing primarily stride frequency and, at a lesser rate, stride length, or by reducing stride frequency while increasing stride length. Increasing velocity through increased stride length is often encountered in medium-sized and larger arboreal mammals. This enhances safety during arboreal locomotion as the longer reach of the forelimbs minimizes branch sway. In contrast, increasing velocity by stride frequency may be better suited for smaller arboreal marsupials, which are subject to insignificant branch sway, as it decreases body oscillations at limb touchdowns (Delciellos and Vieira 2007; Karantanis et al. 2015).

## Gliding

Some marsupials evolved the ability to glide using a membrane of skin called a patagium. Gliding is a simple and efficient form of gap-crossing that allows marsupials to reach substrates that can be quite far apart. There are four separate phases of gliding. At the first stage, the animal either drops in free-fall, or springs roughly horizontally and then drops in free-fall, with both cases having the purpose of obtaining air speed. In the next stage, the marsupial then exerts control over its movement through the air. Shortly after this point, locomotion may be unstable, but after the animal loses more height and raises its air speed, it can maintain steady aerial locomotion. An animal may fail to maintain constant velocity if either glide is short, or in longer glides an animal begins to shift in a different direction. In the final phase, as the animal prepares for landing, it begins to alter the air speeds of its body and adopts a body orientation suitable for landing. Gliding is usually considered to be quite energetically efficient. Work on sugar and feathertail gliders reveal that the cost of gliding is relatively higher than the cost of quadrupedal locomotion. However, when one considers the energy required to descend, cross the gap, and then ascend again, gliding likely

still has energetic benefits (Bishop 2007; Flaherty et al. 2008; Pridmore and Hoffmann 2014). Furthermore, gliding behavior likely reduces the risk of predation.

## Swimming

The thick tailed opossum *L. crassicaudata* is a semiaquatic species of the family of Didelphidae. During a swim cycle, *L. crassicaudata* uses all four limbs in a parasagittal plane, with emphasis on the hind limbs for propulsion. Forelimbs, however, are commonly used for rotational motion and balance. In the power phase, the hind limbs accelerate posteriorly and ventrally, while the digits are abducted and extended. During paddling motion, *L. crassicaudata* shows a homolateral gait; power phase of the forelimb is followed by power phase in the hind limb of the same side of the body. Fur bearing species such as *Didelphis* are presented with a number of issues when swimming. The most apparent of which is the lack of proper buoyancy, due to uptake of water by the fur. Ultimately, this results in horizontal displacement of the body, with compensation needed from the forelimbs to counteract the effect of reduced buoyancy. To ensure adequate breathing during the power phase, *Didelphis*' movement of the forelimbs resulted in upward movement of the nose above water as well (Fish 1993; Santori et al. 2005).

## Conclusion

As a group, the marsupials have evolved a range of locomotor behaviors almost consistent with placental mammals (i.e., no powered flight, obligate swimming, brachiation, or striding bipedalism). They use both quadrupedal, bipedal, and even pentapedal (tail acting as a fifth limb) gaits when moving terrestrially. They are adept at arboreal locomotion, and even use many of the same gait characteristics as the primates (Granatosky 2020). Some marsupial species are even capable of swimming and gliding. Despite this wide range of locomotor

behaviors, the marsupials have largely been ignored as a group compared to their placental counterparts. As such, there remains much to be learned about the locomotor behaviors of this mammalian group.

| Morphology | The biological category concerning size, shape, and general structure of organisms |

## Introduction

Marsupials are a group of mammals mainly characterized by their distinct reproduction. They have a short gestation period followed by an extensive lactation, sometimes inside a pouch, also called marsupium. Despite what the group name implies, several marsupials do not have a pouch. Another interesting characteristic is that all marsupial neonates are altricial, which means that they have an incipient state of development at birth. Young are born excessively small, blind, and without fur but with the ability to climb the mother's inguinal region until they find a teat to attach to and complete its development.

The earliest fossil known of metatherians (mammals most closely related to marsupials than placentals, besides modern marsupials) is from the early Cretaceous of Asia (Kielan-Jaworowska et al. 2004). However, there are few well-preserved records of late Cretaceous metatherians with complete skulls and/or skeletons; most are composed only by jaw fragments and teeth, which already show similarities with modern marsupials. After the mass extinction at the Cretaceous-Paleogene boundary, several metatherian families were extinct. Still in the late Cretaceous, North American opossums from the Didelphimorphia order have a rich fossil record until the middle Miocene. During the Cenozoic, marsupials migrated to southern continents and

spread throughout South America, probably including Antarctica and Australasia regions. The Oceania isolation in late Eocene allowed a great diversification of marsupials, with animals of very different sizes, shapes, habits, and habitats. At first glance, it looks like marsupials are phylogenetically split due to geographical distribution: the cohort “Ameridelphia” (a paraphyletic group that occurs in the Americas) and cohort Australidelphia (a monophyletic group that mainly occurs in the Australasia region). In fact, this division was first proposed by the tarsal morphology of calcaneum and astragalus bones (Szalay 1982), lumping one order found in South America with the Australian marsupials. This classification is still used today and is corroborated by several morphological and molecular phylogenetic analyses.

The cohort “Ameridelphia” is represented by two orders, Didelphimorphia and Paucituberculata. The first one occurs in diverse habitats ranging from southern Canada to Argentinian Patagonia, and the latter occurs in high altitudes of the Andes Mountains, northern and western South America (Astúa 2015; Patterson 2015). The cohort Australidelphia is represented by five orders: Dasyuromorphia, Diprotodontia, Notoryctemorphia, Peramelemorphia, and Microbiotheria. Most of them occur in the Australasia region (Wilson and Mittermeier 2015), except for the Microbiotheria order, which belongs to the Australidelphia cohort although it is present only in South America, in southern Andean forests. This latter is also considered an Australian or Antarctic radiation survivor.

This entry will be categorized into three important topics of (I) morphological design; (II) dentition; and (III) reproductive system and biology. In each topic, the group identification could be by the cohorts or by the orders of marsupials, to facilitate the understanding of their general morphology. The information provided in these sections were mainly based on Vaughan et al. (2000), Szalay (2006), Gardner (2007), Flores (2009), Pough et al. (2012), Feldhamer et al. (2015), and Wilson and Mittermeier (2015). Additional or specific data will be presented with its respective reference.

## Morphological Design/General Morphology

### Skull

The marsupial skull is generally characterized by its tight and small braincase and a flared narrow long nose. When the bone is present, they have ossified auditory bullae that are formed predominantly by the alisphenoid bone instead of the tympanic, basisphenoid bones and/or petrosal, similar to most eutherian mammals. Marsupials do not present the postorbital bar (bone bar behind the orbit), while the jugal bone comprises portions of the jaw glenoid. The palate is very distinct, with a characteristic large vacuity in the posterior part. The angular process of the dentary bone is normally inflected medially and is not present in eutherian mammals, being a synapomorphy of marsupials.

### Skeleton

Most marsupial skeletons barely resemble eutherian skeletons and their morphology are often compared. Notwithstanding, there are a few important differences between them.

In the Australian marsupial foot, a strong unification of digits II and III by the skin, also known as syndactyly, is present in all species from the Diprotodontia and Peramelemorphia orders. The true ecomorphological function of this phenotype is still subject to discussion.

Another feature frequently considered as unique within marsupials are the epipubic or marsupial bones, paired bones articulated in the pubic symphysis, in the pelvic girdle. These bones are ventrally projected to the front of the belly and were considered, for a long time, to function only as a marsupium pouch support. However, there are registers of epipubic bones in monotremes (platypus and echidnas) and also the cyodonts, the non-mammalian group that originated modern mammals. The latter were and oviparous species that did not carry their young during development. Besides that, it is known that these bones, in addition to two extra muscles, perform a cross-couplet linkage during marsupial locomotion (Reilly and White 2003). These two non-

excluding hypotheses for epipubic bone function continues in discussion.

### Ameridelphia Morphology

The Ameridelphia group is composed of two orders, Didelphimorphia and Paucituberculata. They are small to medium size opossum-like marsupials with very conserved characteristics. Considering the Didelphimorphia order (Fig. 1), they have a long snout with many vibrissae, round eyes, and big flattened ears. The coloration is variable, with individuals presenting dark gray or brown tones, with some having a cream-colored belly. Some species with lighter shades may be brownish-orange and white, with details in black or gray, especially in eye masks. Body length ranges from 10 to 95 cm and can be as light as the 30 g *Tlacuatzin* or as heavy as the 5.9 kg *Didelphis*. Body shape may be associated with its locomotion habit. Terrestrial and scansorial species tend to be elongated while walking and form a lumbar curve when sitting, standing, or jumping. Arboreal species are likely to walk with the limbs flexed because of their gravity point, which needs to be closer to the substrate (Argot 2001). The contrasting animal in this group is the unique and truly semiaquatic marsupial species, *Chironectes minimus*. With a hydrodynamic body, dense and -water-repellent fur and also a webbed feet, is the most adapted didelphid to swim. There are no fossorial or gliding marsupials in this group. All

Didelphimorphia have a prehensile tail, but it may be short, as in the short-tailed opossums *Mondelphis*, long or fat as in the fat-tailed opossum *Thylamys*, and especially thick, as in the thick-tailed opossum *Lutreolina*. In Didelphimorphia, the skull is homogeneous, with a few differences related to size and shape, preserving their general morphology. The rostrum is long and the sagittal crest is prominent. *Caluromys* shows a rounded palate, where a shift in orientation occurs between the upper post-canine rows and the development of a strongly curved post-palatine torus, which are not known for any other marsupial so far (Flores et al. 2010). Their feet are plantigrade, and all species have an opposable and clawless thumb, being probably inherited from arboreal ancestors.

The Paucituberculata order (Fig. 2) is known as a small and terrestrial shrew-like opossum due to its long snout and small eyes. They have a distinct lip flaps right below and anteriorly from the vibrissae, and also flattened ears smaller than Didelphimorphia. Their feet are unspecialized (not fused) and do not have opposable thumbs. The tail is not prehensile and can store fat seasonally, expanding from 4–5 mm (in diameter) during summer to 9–11 mm in the winter. Their size generally ranges 15–25 cm, and they can weigh 25 g as in the Dusky shrew opossum (*Caenolestes fuliginosus*) and up to 53 g as in the Sangay shrew opossum (*Caenolestes sangay*). The dorsal coloration does not diverge from black, gray, and dark brownish and they could or could not present a whitish belly.

### Australidelphia Morphology

As mentioned earlier, the Oceania isolation during the Cenozoic Era supports the significant diversification of Australian marsupials, when compared to American marsupials. In Australian marsupials, their entire body can be remarkably different, even in the same order or family. They also have huge differences in size. The smallest ones are the pygmy possums, ranging from 5 to 12 cm, and they could weigh between 10 and 50 g. The largest ones are the red kangaroos, with up to 2 m height and a body mass up to 90 kg. To comprise all these distinct designs, this section will be divided according to their orders and main differences.

#### Dasyuromorphia

This order comprehends two families, Dasyuridae and Myrmecobiidae. Dasyuridae (Fig. 3) are known as carnivorous marsupials, and some of them have similar skull to Didelphimorphia order. Their forefoot has five digits, and the hindfoot can have four or five digits, with a clawless thumb that could be vestigial or absent in some cursorial genera, such as the Tasmanian devil, *Sarcophilus*. Except for the long-limbed jumping kultarr (*Sminthopsis laniger*) and the cursorial quoll (*Dasyurus viverrinus*), they all have plantigrade posture. The tail is never prehensile. Their sizes range from 10 cm and 3.6 g in

very small possums as Planigale, with 10 cm and 3.6 g to Tasmanian devils (*Sarcophilus*) that can reach 131 cm and weights up to 14 kg. Myrmecobiidae is represented for only one species, the numbat. It is a slender and small long-nosed anteater, with a long, narrow and sticky tongue to capture termites. The species have a colorful dorsum with an orangish, black, and gray gradient, with well-marked lighter strips and a non-prehensile tufted tail.

#### Diprotodontia

The most diverse order of marsupials have several and extensive radiations. It is comprised of 11 very distinct families (Wilson and Mittermeier 2015), organized in 3 suborders: Vombatiformes, Phalangeriformes, and Macropodiformes (Fig. 4).

Vombatiformes comprise the koalas and the wombats. Koalas can range up to 82 cm length, and males can be two times heavier than females. The species significantly changes between South Australia population, which are heavier and darker than North and East Australia population. They have rounded tufted ears, a large and flat nose, and eyes with a vertical iris. They have opposable clawless thumbs and a rudimentary tail. The fur is mostly gray on the dorsum and white belly, with dark brownish tones on the rump in southern populations. Wombats resemble a terrestrial and burrowing koala, with smaller ears and short and large nose. They could be up to 115 cm in length and 30 kg, and pelage can be gray or brown, some with yellowish tones. In contrast with the koala, they have a poorly developed cecum and produce cubic feces.

Phalangeriformes have five families which include arboreal primate-like forms as cuscuses and large opossums; great, lesser, and feather-tailed gliders; pygmy possums; and the exclusive nectarivorous marsupial, the honey-possum. They are medium-small sized, ranging from 10 cm to 1.2 m length, and can weight up to 4.5 kg. The fur color greatly varies between the families, and they can be dorsum-striped as gliders and honey-possums, or with exceptionally different spotted patterns as several cuscuses, white with gray, black, and also brown yellowish stains on

the dorsum. Some of them have a prehensile tail as in the ring-tailed opossum. In the two glider forms, the gliding membrane is formed by strong connective tissue from the elbow to the ankle, comprising all the lateral side of the body.

Macropodiformes are the hopping marsupials, including bettongs, potoroos, musky rat-kangaroos, wallabies, and kangaroos. They all have short forelimbs and large hindlimbs and hindfeet. The first two represents the Potoroidae family; they are small, ranging from 55 to 85 cm and up to 3 kg. It can present greyish, brownish, or yellowish dorsum fur, with a lighter belly. They have medium furred ears, small eyes, and naked nose. The tail can be prehensile. The third mentioned, musky rat-kangaroos are the smallest macropodiformes ranging up to 45 cm and 0.5 kg. The body fur is mostly orangish brown, with a prehensile naked tail, short naked ears, and small rounded eyes. The rostrum is short. The last two forms, wallabies and kangaroos, are lumped in Macropodidae, the largest family in the order Diprotodontia. They can reach up to 2 m in height and weigh 90 kg in the red kangaroos. They could be terrestrial or arboreal, with a huge variation on pelage color, varying from homogeneous gray to flashy yellow and brownish as in some tree-

kangaroos. Sexual dimorphism of size is notable, with males significantly heavier than adult females. Males can also be very muscularized, which serves the purpose of being able to box with other males, for sexual competition. The rostrum is long, usually, and they have movable large ears, and eyes size can vary. The tail is robust and provides equilibrium during rapid bipedal hopping locomotion. Their big rump is useful as low gravity center to help them maintain balance while jumping.

#### Microbiotheria

In this order, there is only one extant species, the monito del monte *Dromiciops gliroides* (Fig. 5). The species is small, 15–25 cm in length and weighing up to 32 g. Their snout is short when compared with other opossums, with medium-sized ears and eyes, the latter with a rounded well-marked mask. They have dense body fur with a blended pattern color with a white venter and a mixed cream, yellow, brown, and grayish dorsum. The tail is semi-prehensile, and it stores fat, in case of food scarcity and/or cold temperatures to enter in a period of hibernation (Rageot 1978; Palma and Valladares-Gómez 2015). They have a greatly enlarged tympanic bullae which

includes an ectotympanic bone, an unknown feature among other marsupials (HersHKowitz 1992).

#### Notoryctemorphia

This noteworthy order is represented by the unique marsupial mole (Fig. 6), presenting many congruent characteristics with eutherian moles. The species is small, completely blind with vestigial eyes covered by skin, the ear does not have a pinnae, and the nose is similar to a hard shield with a slim incision. Limbs are robust, spread positioned and closer to the ground, like a “sand-swimmer”, with their main specializations concentrated in (but not restricted to) the forelimb (Warburton 2006). The fore claws of digits III and IV are greatly expanded and spade-shaped, while in the hindfeet the first digit has a nail; the II,

III and IV digit are enlarged; and the fifth digit is vestigial. Five cervical vertebrae are fused to stiffen the neck while digging and epipubic bones are reduced. The fur is long and bright white or yellowish red due to sand stains (Aplin 2015).

#### Peramelemorphia

This order comprises bandicoots and bilbies (Fig. 7). Both present non-prehensile tails and lack clavicles. Bandicoots have a slender rostrum with very lengthy nose. The smallest bandicoot can weigh up to 100 g and the largest up to 5 kg. In general, they have dorsum fur darker than the belly, and the dorsum can vary from gray to orangish brown. They present short forelimbs with the II, III, and IV digits well developed with claws and elongated hindlimbs with a very prominent fourth digit. Bilbies can range from 50 to 85 cm in length, and sexual dimorphism in size is evident; males can range to twice the size of females, up to 2.5 kg. Due to its hopping habits, and long nose and ears, they resemble a rabbit. Therefore, they are a surrogate of Easter bunnies. Australians celebrate the “Easter Bilby” instead. They have silky and mostly gray fur on the dorsum and a white belly, with a tufted tail abruptly divided anteriorly in black fur and posteriorly in white fur.

#### Dentition

The marsupial molar teeth are tribosphenic or tritubercular, due to three sharp and large cusps

disposed in a triangular pattern. Upper molars are formed by the paracone, protocone, and metacone cusps. Lower molars, otherwise, have a paraconid, protoconid, and metaconid as sharp cusps. Nevertheless, particularities of marsupial dentition different from eutherians are a well-developed styler shelf present only on the upper molars in the labial side.

Marsupials have a particular pattern of dentition, with distinct numbers of upper and lower incisors. Primary (deciduous, “milk-teeth”) incisors and canines are vestigial and never erupt, being reabsorbed when the secondary teeth (“permanent-teeth”) erupt. The first and second premolars are deciduous and caniniform, the permanent form does not develop. The third premolars have two forms, the first is a deciduous (“milk teeth”) molariform teeth and also represented as dP3. This form helps the young to shift their feed pattern from liquid to solid and starts mastication activity. As the animal grows up and other molars develop, the second form appears as a permanent caniniform premolar (or P3), that erupts and takes place in the occlusal plane. Sometimes the dP3 is not lost immediately after the P3 eruption, so it is common to find both teeth coexisting for a while in the jaw. The four molars are unreplaced primary teeth (Cifelli and Muizon 1998). The general dental formula of the cheek teeth in marsupials is three premolars and four molars, usually represented by  $P3/3$  and  $M4/4$  or  $P_3^3$  and  $M_4^4$ .

### Ameridelphia

The dental formula of Didelphimorphia is I 5/4, C 1/1, P 3/3, M 4/4 = 50. They have small, delicate and unspecialized incisors, canines are robust and large, and molars do not have critical changes. Although their feed habits are highly diverse, it is not strong enough to override the pre-existing morphological differences in molar shape that occur among didelphids (Chemisquy et al. 2015).

In Paucituberculata, the dental formula is I 4/3-4, C 1/1, P 3/3, M 4/4 = 46 or 48. The distinguishing feature about them is their first lower incisors that are strongly procumbent and

large, while the others incisors, the canine, and the first premolar are narrow and unicuspid. Their lower incisors are used like rapiers to stab prey (Kirsch 1977), and it appears to be homologous with the second lower incisors of didelphids.

### Australidelphia

#### Dasyuromorphia

The dental formula is I 4/3, C 1/1, P 2-3/2-3, M 4/4 = 42 or 46. They have small, pointed or blade incisors with large sharp-edge canines. Their upper molars have three sharp cusps that are adapted to an insectivorous and carnivorous diet.

#### Diprotodontia

The name of Diprotodontia order is due to their modified lower incisors, which are procumbent and project forwardly, similar to rodents (Greek *di* = two, *proto* = first and *dont* = tooth). This order is comprised of herbivorous and omnivorous extant forms. Their dental formula is variable within the families.

In Vombatiformes, the dental formula of koalas (Phascolarctidae) is I 3/1, C 1/0, P 1/1, M 4/4 = 30 and in wombats (Vombatidae) is I 1/1, C 0/0, P 1/1, M 4/4 = 24; in the latter, teeth are open-rooted and grow continuously, unique in marsupials and similar to rodents.

In Phalangeriformes, the pygmy possums (Burramyidae) dental formula is I 3/1-3, C 1/0, P 2-3/2-3, M 3-4/3-4 = 30-42, with the first incisor much larger than the other two. In cuscuses and possums (Phalangeridae), dental formula is I 3/2, C 1/0, P 2-3/2-3, M 4/4 = 36-40, with a second deciduous premolar. Ring-tailed and greater gliders (Pseudocheiridae) have I 1-3/1-2, C 1/0, P 1-3/1-3, M 4/4 = 26-40, while lesser gliders (Petauridae) have I 3/1-2, C 1/0, P 3/1-3, M 4/4 = 34-40, with the three premolars single-cusped and crest-shaped crowns in molars. The tiny honey possums (Tarsipedidae) have fragile jaws that are not able to chew, and the dental formula is reduced due to its nectarivorous habit, I 2/1, C 1/0, P 1/0, M 3/3 = 22. Feather-tailed gliders (Acrobatidae) have uncertain dental formula, usually I 3/1, C 1/1?, P 3/3?, M 3/3 = 36, and can differ from feather-tailed possums.

In Macropodiformes, the dental formula in the Potoroidae is I 3/1, C 1/0, P 1/1, M 4/4 = 30, with first incisors larger than the other two and short diastema, with well-developed upper canine and a large blade-like premolar. In Macropodidae the dental formula is variable, I 3/1, C 0-1/0, P 1/1, M 4/4 = 28-30, with upper incisors and procumbent lower incisors usually well-developed. They have a long diastema and are lophodont, with high-crowned molars.

#### Microbiotheria

The dental formula is the same as the American order Didelphimorphia, but their lower canines are smaller than the didelphids. The four lower incisors are uncrowded and evenly spaced in line (Hershkovitz 1992).

#### Notoryctemorphia

Their teeth are unusually separated from each other. The dental formula is variable, I 3-4/3, C 1/1, P 2/2-3, M 4/4 = 40-44. Incisors, canines, and premolars are unspecialized, unicuspid, and little sharp, while the last upper premolars have two cusps (bicuspidate). The upper molars are tritubercular and the lower molars lack a talonid.

#### Peramelemorphia

They are characterized in general by their insectivorous sharp dentition and also are polyprotodont, with four or more incisors on each side of the jaw. The general dental formula is I 5/3, C 1/1, P 3/3, M 4/4 = 46-48, but *Echymipera* bandicoots have only four upper incisors. Peramelemorphians have small incisors and well-developed canines and molars which can be tritubercular or quadritubercular, with fewer cusps.

## Reproductive System and Biology

Marsupial general anatomy is commonly compared with some eutherians, due to size and shape similarities. The reproductive apparatus of these two groups, however, is remarkably different.

In females, the oviducts are separated by the ureters, in other words, the ureters pass in between the oviducts. This impedes the oviducts from meeting in the middle to form a single median uterus and vagina, one of the limiting features that possibly explains the small size of marsupial neonates (Renfree 1993). The reproductive tract consists of two lateral vaginae only for sperm passage, and it is connected anteriorly, following the end of the uteri. During the first birth, a median vagina or pseudovagina is formed, a canal only for the neonate passage. Concerning the placenta, it is commonly stated that marsupials do not have one. In fact, all marsupials and some eutherians have a rudimentary choriovitelline placenta, which is developed from the yolk sac and considered as a primitive placenta. Bandicoots, koalas, and wombats develop an intermediary chorioallantoic placenta in late gestation, formed from the union of chorionic and allantoic amniote membranes, similar with eutherians placenta.

In most males, the penile glands is bifid, to fit in the two lateral female's vagina. Unlike eutherians, peduncular testicles from marsupial males are in front of the penis. An interesting exception occurs in the marsupial mole (Notoryctemorphia). Due to its digging habit, the testes are located inside the body, between the abdominal wall and the skin, so there is no visible scrotum. In American marsupials, males do not have seminal vesicles, ampullary, or preputial glands, as seen in eutherians. In *Didelphis*, the gonadal differentiation occurs early, with 9 days in the marsupium as altricial neonates. At this same time, the scrotum and the marsupium (in females) are visible in the young (Nogueira 2006). In Microbiotheria, the scrotum has a very short peduncle, being almost sessile.

Both sexes present an external cloaca instead of a separated reproductive and excretory apparatus, except the male of the American water opossum (*Chironectes*), which lacks a cloaca and has separated anal and urogenital openings (Nogueira et al. 2004). In Microbiotheria, the cloaca is significantly different, opening on the ventral side of the base of the tail, as occurs in monotremes (platypus, equidnas) and also in reptiles.

## Pouches

The name marsupial comes from the marsupium/pouch, a structure in the abdomen to keep and protect the litter during external development. Although it is expected that all marsupials have pouches, due to iconic kangaroos with their well-developed pouch, many of them do not have a marsupium, especially the American marsupials. This structure has several morphological changes during reproduction, such as change in color, size, and shape, and could secrete fluids (Hesterman et al. 2008). This variation also occurs in pouchless species but in the female inguinal region in both Australian and American marsupials (Calaby and Taylor 1981; Guilhon et al. 2019).

In Didelphimorphia, the pouch is present only in medium-large opossums (6/18 genera) as *Didelphis*, the woolly-possum *Caluromys*, the black-shouldered opossum *Caluromysiops*, thick-tailed opossum *Lutreolina*, and the black four-eyed opossum *Philander*. The brown four-eyed opossum *Metachirus* has a similar size but lacks a pouch. The water-opossum *Chironectes* is the only American marsupial in which both sexes have pouches and it is notably specialized: a sphincter is responsible for closing females' pouches, sealing it entirely and preventing incoming water. On the other hand, male pouches protect their scrotum from water and cooling, keeping spermatogenesis at the optimum level. No other species in the Didelphimorphia and Paucituberculata orders have pouches, maintaining their litter in the inguinal region during the teat-attachment phase, and avoiding moving long distances with the neonates. After this first development phase, the female leaves the nestlings unattended while foraging. In Microbiotheria, females of the only extant species *Dromiciops gliroides* possess a pouch with four nipples. A further characteristic of this order is that pouch-young males lack mammary anlagen (the first discernible group of cells destined to form a mammary gland) during development, classified as another morphological feature shared only with Australian marsupials (Frankham and Temple-Smith 2012).

Most of the Australian marsupials, however, have pouches, in variable forms. It could be well-developed as in several diprotodonts (e.g.,

kangaroos, wallabies, koalas, wombats, etc.), poorly developed (e.g., some dasyurids) or absent (e.g., sugar gliders, mouse opossums, honey-opossum). The extinct Tasmanian tiger *Thylacinus* had pouches in both sexes. In females, the pouch opening was faced posteriorly, while males had a rudimentary pouch, believed to protect the penis and scrotum during cursorial running. Posteriorly oriented pouch openings in females can have several functions, as in wombats, who can continue to dig with pouch-young, protecting them from the dirt entering. This also occurs in the mole *Notoryctemorphia*, in which a fold in the abdominal wall divides the pouch into two compartments, and each one contains a nipple (Grassé 1955). In males, the marsupium is sometimes inconspicuous, consisting of a slight transverse skin fold that resembles the internal conformation of the female's pouch.

## Neonates

Marsupial newborns are altricial (Fig. 8), which is characterized by the pup being blind and hairless, with a very reduced mobility and with a high chance of not surviving without maternal parental care. The neonate is born with the minimum anatomical development necessary to live outside the uterus: mouth, forelimbs and deciduous claws, being able to climb the female's inguinal region to find a teat and attach to it until its development is completed. This teat-attachment phase is variable among

**Marsupial Morphology, Fig. 8** Altricial neonates from *Didelphis albiventris*, blind, hairless and with a very reduced mobility. Photo: Diego Astúa

species but always exceeds the gestation period. The number of nipples and litter size are not always compatible. The number of nipples varies from 2 in Notoryctemorphia and some Dasyuromorphia to more than 12 in Didelphimorphia species. Individual variation in this number also occurs within a species. This expresses a very selective phase for the newborn, in which only the first one able to find a teat will survive.

## Conclusions

Marsupials are a group of mammals characterized by their peculiar reproductive strategy, with a short gestation period and a long period of post-partum development and lactation, which could happen inside a marsupium pouch. They are commonly divided in two groups, American and Australian marsupials. The first represents the generalized opossum-like forms, weighing from 30 g to 5.9 kg, terrestrial, arboreal, scansorial and containing the only truly water-adapted opossum. Most of them are small and pouchless species with similar skull/skeleton and dental formula, usually appropriate to an omnivorous diet. Australian marsupials, however, are more diverse in size and shape, including kangaroos, koalas, sugar gliders, marsupial rats and marsupial moles, weighing from 10 g in the honey-opossum to 90 kg in the red kangaroo. Their skull and skeleton can be significantly different from each other. Most of them have pouches, which could be well or poorly developed, with posterior or anterior openings. All female marsupials possess two lateral vaginae for reproduction, and one medial pseudovaginal canal developed only for the neonate birth, while most male marsupials have a bifid penile gland, positioned posteriorly to their scrotum. The marsupial young are born in a very altricial state, blind, hairless and with very low mobility, highly dependent of the maternal care to survive.

Martha H. Wilson (1929–2010) was a member of one of the most influential families in psychology. Her father was Harry Helson (1898–1977), who received the Distinguished Scientific Contribution Award of the American Psychological Association in 1962, among other career awards, in part for his development of Adaptation Level Theory. Her husband of 62 years was William August (Bill) Wilson, Jr. (1924–2017), who earned M.D. and Ph.D. degrees before a long and productive career in biopsychology and

neuroscience. Martha's older brother Henry, a professor of mathematics, married Ravenna Mathews Helson (1925–), a leading scholar in the psychology of women and the study of personality across the lifespan. As for Martha Wilson, she made significant and lasting contributions to physiological and comparative psychology, both through scholarship and leadership. She was a long-time professor of psychology and behavioral sciences at the University of Connecticut who studied the physiology of vision, discrimination learning, and category learning in rhesus monkeys (*Macaca mulatta*) and bush babies (*Galago*). She was also elected to lead the discipline in numerous roles, including as the 1986–1987 President of the Division of Physiological and Comparative Psychology (Division 6) of the American Psychological Association.

## Personal and Professional History

Martha Alice Helson was born January 7, 1929, 18 months after her brother Henry, to Dr. Harry and Lida G. (nee Anderson) Helson (1900–1979?). Martha Alice was practically raised on college campuses, principally at Bryn Mawr where her father was professor of psychology for many years. Her mother had earned undergraduate and master's degrees in French literature before marrying; later, she authored several published remedial-reading texts, workbooks, and teacher manuals. When World War II broke out, Dr. Helson moved his family to Foxboro, MA, for several years to work on Navy-funded human-factors research. Martha Alice was sent back to a Quaker boarding school in Pennsylvania, where she would graduate from Westtown Friends School in 1946 before enrolling in Bryn Mawr College.

Martha was encouraged by her father to prepare for a career as a psychiatrist to bring scientific rigor to the area that was still dominated by psychoanalytic thought, and indeed she completed all of the coursework required for admission into medical school. However, Martha gravitated to psychology, which used research methods from the natural sciences for investigating the behavior

of living organisms. Her own independent research program began during these years, as she undertook a study of color vision under the supervision of physics professor Walter C. Michaels. In 1950, Martha H. Warren – prior to her senior year, she had married Robert Warren, Jr., whom she had met at a Quaker work camp – graduated with honors with a degree in psychology from Bryn Mawr.

The years between undergraduate and graduate school were momentous for Martha, both professionally (e.g., she worked on a research project that resulted in her first two scholarly publications: Helson et al. 1952, 1956) and personally (e.g., she gave birth to a daughter, her marriage ended). In 1952, she enrolled at Yale University for doctoral study in psychology, working initially there with Dr. Lloyd Beck and Dr. Walter Richard Miles. In her second year at Yale, Martha met Dr. Burton S. Rosner, an assistant professor in need of a research assistant to help with a funded project to study the neural signals corresponding to tactile stimulation in guinea pigs and rabbits. Although physiological psychology was a new area for Martha, she embraced the topic without hesitation. After a year in this research project, Martha planned to develop a dissertation project under Professor Rosner's direction on somatosensory mapping; however, an opportunity to develop her skills in electrophysiology at the Hartford (CT) Institute for Living changed those plans.

At the Institute, Martha met a powerhouse team of scientists at the Laboratory of Neurophysiology, directed by Dr. Karl Pribram. Other scientists in Pribram's laboratory included new Ph.D.'s Mortimer Mishkin and Larry Weiskrantz, and a new M.D. named William A. (Bill) Wilson, Jr., who would receive his Ph.D. from Berkeley the following year. Each of these men would profoundly impact the science of brain and behavior, but two would have a particularly large influence on Martha herself: Dr. Pribram became her mentor, collaborator, and friend across her career. Dr. Wilson, also a life-long collaborator, became the love of her life, husband of 62 years, and father of her children. Martha and Bill married in 1954. Martha worked at the Institute for Living from that same year until 1959.

After learning neurosurgery in Hartford, Martha changed her dissertation topic to an attempt to link structure and function in the posterior association cortex of the rhesus monkey brain. Her 1955 dissertation, titled *Effects of circumscribed cortical lesions upon somesthetic and visual discrimination in the monkey*, was approved by a committee consisting of Professors Rosner, Pribram and Frank A. Beach. The study linked the inferior temporal region to visual but not somatosensory discrimination learning, and posterior parietal cortex to tactual but not visual discrimination. The work was subsequently published in *Journal of Comparative and Physiological Psychology* (Wilson 1957).

In 1958, Bill accepted a faculty position at the University of Colorado, and so Martha and Bill moved with the children to Boulder. Martha was appointed Visiting Professor and began teaching while writing-up data collected in Hartford (Wilson et al. 1960). Research facilities were not ideal, however, and an offer to Bill from Dr. M. E. Bitterman, chair of psychology at Bryn Mawr brought the Wilson family “home” to Martha’s alma mater. Martha accepted a research associate position on Bill’s NIMH-funded project, studying visual and tactual learning-set formation in a laboratory with nearly 100 monkeys (Wilson and Wilson 1962; Wilson et al. 1963; Wilson and Wilson 1964). She also taught at nearby Rosemont College. The research and publications continued when the Wilsons moved the project, and their family, to the University of Connecticut in 1964 (e.g., Oscar and Wilson 1966; Wilson et al. 1968).

Dr. Martha Wilson spent the remainder of her career at the University of Connecticut, until her retirement in 1987. For the first 9 years, she remained in a full-time research position, conducting experiments in the rhesus monkey laboratory that UConn had built for the Wilsons in Storrs. When the Wilsons returned from Bill’s 1972 sabbatical-year visit to Duke University – during which time Martha worked as a NIMH research fellow with Dr. Irving Diamond on a study of the neural mechanism of visual attention in bush babies (e.g., Soper et al. 1975) –, Martha was appointed as Professor of Psychology at the

University of Connecticut. The faculty position allowed Professor M. Wilson to teach and mentor students, and to apply for grants as principal investigator. Soon, she had obtained a large grant from the National Science Foundation, established a bush baby colony in Storrs, and began studying the behavioral consequences of lesions in the visual cortex of the prosimians. She also continued to study visual processing in rhesus monkeys.

Dr. Martha Wilson with one of the monkeys at the laboratory in Storrs, CT

In the late 1970s, Professor Wilson began to consider whether the kinds of research she had conducted with monkeys and prosimians could be applied fruitfully to human populations. She invested her 1979 sabbatical in learning the protocols for working with people who had suffered brain damage. Always ready to learn from the leaders of the field, Dr. Wilson traveled to the Montreal Neurological Institute to work under the supervision of famed neuropsychologist Dr. Brenda Milner and her team. From her first day at the Institute, Dr. Wilson was engaged in neuropsychological assessment – both as a clinical researcher, and also by serving as a normal-control volunteer participant in all of the ongoing studies. The lessons about studying brain-behavior relations in humans, often applying the testing paradigms and questions (if not the physiological methods) of her own work with nonhuman primates, were taken back to Storrs after Professor Wilson’s sabbatical. There, she began studying how organisms (humans,

monkeys, prosimians) organize or categorize sensory information. Together with her graduate advisee Barbara Streitfield, Dr. Wilson challenged the popular “speech is special” view of categorical perception, which argues that language allows humans to distinguish stimuli across category boundaries better than stimuli that are equally different but within category boundaries (e.g., to discriminate better between a blue stimulus and a green stimulus than between two blue stimuli that differ by the same amount of hue, but share a linguistic label). For Streitfield’s dissertation studies (subsequently published as Streitfeld and Wilson 1986), she and Dr. Wilson showed these same category-boundary effects with non-linguistic stimuli. Human participants’ visual and kinesthetic discrimination performance was better between than within categories. Critically in this work, category boundaries were computationally determined by applying the logarithmic formula that had been theorized in Gestalt-psychology inspired “Adaptation-level Theory” – one of the primary contributions championed by Martha Wilson’s father Harry Helson. This application of Adaptation-level Theory has important ongoing implications for a wide range of topics in psycholinguistics and cognitive psychology, including for the comparative study of cognition.

### Selected Significant Accomplishments

Dr. Wilson retired from the University of Connecticut and professional responsibilities in 1987, at just 59 years of age, but invested great energy over the subsequent 33 years of her life into community service and advocacy for social and political causes. For example, she volunteered her time, effort and expertise at the Northeast Correctional Institute, visiting the Connecticut prison three times per week for 8 years to teach inmates literacy skills, psychology classes, GED preparation, and other topics. She also remained active in anti-war and social-justice issues until her death on April 6, 2020 at her home in Block Island, RI.

Although her professional career lasted less than four full decades, Dr. Wilson authored 40 publications, attracted significant federal grant support,

taught and mentored students, and invested heavily in disciplinary service, particularly for the American Psychological Association (APA). For her scholarly work, Dr. Wilson was recognized as a Fellow of APA Divisions 1 (General Psychology), 3 (Experimental Psychology), and 6 (Physiological and Comparative Psychology).

As the name suggests, APA’s Division 6 represented two different but complementary sub-fields. In its 75-year history, few scholars served the division as extensively as did Dr. Martha Wilson, and arguably no one’s program of scholarship better represented *both* of its membership constituencies. Dr. Wilson was a physiological psychologist who studied the neural mechanisms of vision in monkeys and prosimians. Her behavioral investigations of intersensory learning were mainstream comparative psychology, as were her innovative studies of category learning that bridged animal research with human clinical neuropsychology. In a definitive history of Division 6, Dewsbury (1996) described Martha Wilson (along with Brenda Milner, Karl Pribram, Mortimer Mishkin, and a few others) as “regulars who kept Division 6 alive” (p. 55). Dr. Wilson served as the organization’s temporary Secretary-Treasurer when Division 6 was reestablished in 1963, after its 14-year period of merger with Division 3, and she was elected to this office again for 1969–1971. She subsequently served the division in elected offices of Member-at-Large on the Executive Committee (1974–1977) Representative to Council (1977–1980), President-elect (1985–1986), President (1986–1987), and Past-president (1987–1988). For her 1987 presidential address, Professor Wilson discussed brain mechanisms in categorical perception. A chapter *Categorical Perception: The Groundwork of Cognition*, edited by Stevan Harnad, reviews this research (Wilson 1987).

Included in this legacy is Dr. Wilson’s record of accomplishment during an (ongoing) era in which women faced challenges beyond those of their male peers. Like other female scholars, Martha Wilson made difficult choices and sacrifices in professional development in order to have children. Her long, happy, and successful marriage to Bill Wilson came with academic costs, both from institutional biases and anti-nepotism rules and

also from less overt negative attitudes and treatment. Although she benefited from strong and effective mentors and collaborators, academic and professional opportunities and recognitions were likely slower to come to Martha Wilson and other female scientists than to males with comparable academic and research records. Nevertheless, Dr. Wilson expressed gratitude for the support, acceptance, and honors she received from psychology, and noted in the foreword of her memoir that she was writing “in the context of an era that allowed me, if somewhat painfully at times, to become a different person than most women who lived in past times” (Wilson 2010).

## Definitions

Martin Daly is an evolutionary psychologist who received his Ph.D. from the University of Toronto. Margo Wilson was an evolutionary psychologist who received her Ph. D from University College

London. Together, Daly and Wilson applied an evolutionary perspective to crime statistics to provide an explanation for patterns of violence and homicide in modern human societies.

Martin Daly and Margo Wilson were a husband-wife research team who, together, investigated the evolved functions of human aggression until Wilson's death in 2009. A great deal of Daly and Wilson's work focused on human aggression and, in particular, homicide. Their 1988 book *Homicide* applied an evolutionary perspective to violent crime statistics from urban cities and offered explanations for these patterns of violence in the context of evolved psychology. Daly and Wilson dispelled a number of supposed inconsistencies between evolutionary logic and observed crime statistics in industrialized, Western cities like Chicago and Detroit. They argued that available data on violent crime are vulnerable to misinterpretations and erroneous conclusions, such as the belief that the majority of homicides are committed against kin. However, the factual basis of this claim relies largely on one's definition of kin. The kin altruism hypothesis predicts that, because individuals share roughly 50% of their genes with full siblings, biological children, or parents, an individual may aid copies of his or her own genes by behaving altruistically toward these individuals (Hamilton, 1964). Therefore, if humans regularly engaged in the killing of genetically related kin, this would pose a considerable contradiction between patterns of human aggression and the theory of evolution by natural selection (Darwin, 1859). Daly and Wilson explain that crime statistics like those from Chicago and Detroit do not present a conflict with evolutionary theory because many of the homicide victims reported as "kin" in police records are not genetically related to the perpetrator. In fact, many of these homicides are perpetrated by husbands, against their wives. Daly and Wilson take caution to avoid the implication that wife-killing may be adaptive. Rather, they explain that the supposedly high frequency of kin-killing suggested by violent crime statistics may be explained, at least in part, by men killing their spouses. Although killing one's intimate partner may certainly incur adaptive costs, Daly and Wilson argue that wife killing is likely an unintended byproduct of spousal

abuse which, itself, is intended to prevent or punish partner infidelity.

Another contentious aspect of human behavior addressed by Daly and Wilson in *Homicide* was infanticide, specifically the killing of infants by their mothers. At first glance, infanticide might appear to be in conflict with evolutionary logic, as not only are women killing an offspring who shares half her genes, but also they have seemingly wasted the time and investment involved in gestating and birthing the child. However, as Daly and Wilson explain, for women who find themselves giving birth under especially unfavorable conditions, the costs of keeping the child might be much greater than committing infanticide and may be outweighed by the potential benefits of waiting to raise a child under more favorable conditions. Daly and Wilson also point out that women are much more likely to kill their infant children when they are young and/or unmarried, suggesting that women who are poorly provisioned might be better off in the long term by committing infanticide and having another child when they have secured investment from a male partner.

Daly and Wilson's body of work represents a landmark contribution to the literature on evolved human psychology; however, their research is also notable for inspiring numerous subsequent studies investigating violence and aggression using an evolutionary perspective. For example, many studies have investigated intimate partner violence from an evolutionary perspective and have consistently found that men are more likely to use violence against their partner when they suspect her of committing infidelity (e.g., Buss & Shackelford, 1997). Further, researchers have observed that younger women appear to be at increased risk of being killed by their partners (e.g., Shackelford et al., 2000). The researchers suggested that, for men, the reproductive costs associated with a female partner's infidelity are much greater when the female partners are relatively younger. As a result, a young woman's infidelity might elicit greater sexual jealousy, and subsequently more severe violence by her male partner. As a whole, these findings support several of Daly and Wilson's main arguments in *Homicide*, such as that selective pressures in the

ancestral environment likely favored violent, aggressive responses from males when they suspected their partners of infidelity, and that such responses reduced the likelihood that men would unwittingly invest resources in genetically unrelated offspring.

Daly and Wilson have also published several papers on nonhuman animals (e.g., Daly et al., 1990). Martin Daly, in particular, has conducted research on foraging habits in kangaroo rats (*Dipodomys*, Heteromyidae). One such study observed that kangaroo rats are more selective in their foraging habits when predation risk in their environment is relatively high (Leaver & Daly, 2003), and a separate study reported that kangaroo rats expend greater effort to store more desirable food items (Leaver & Daly, 1998). Additionally, Daly et al. (1984) conducted a descriptive study, in which they detailed the living conditions and breeding procedures of their captive, kangaroo rats, and in another study, Wilson et al. (1985) described the estrous cycle of captive kangaroo rats.

Recent published works by evolutionary scientists have emphasized the downward trend in violence (Pinker, 2011) as well as the relative lack of aggression in humans compared to other species, and especially compared to our closest living primate relatives (Wrangham, 2019). Nevertheless, aggression is undoubtedly part of human evolutionary history, and Daly and Wilson's research on violent human behavior and cognition has yielded substantial contributions to evolutionary psychology.

## Masseter Muscle

Ravi Kant Narayan

Department of Anatomy, All India Institute of Medical Sciences (AIIMS),  
Patna, India

## Synonyms

[Muscle of mastication](#)

## Introduction: The Muscle and Its Fascia

Masseter belongs to the group of the muscles for mastication (others are temporalis, lateral pterygoid, and medial pterygoid). The epimysium of masseter along with the superficial lamina of the deep cervical fascia of the neck covering the parotid gland forms a thickened unyielding parotid – masseteric fascia or parotido – masseteric fascia. This fascia separates structures overlying the surface of masseter, the parotid

duct, the buccal branch of the facial nerve, and interconnecting branches from the mandibular nerve. Anteriorly, the parotid – masseteric fascia blends with the epimysium of buccinator muscle after crossing the surface of buccal pad of fat and below the lower border of mandible, parotid – masseteric fascia is continuous with the deep cervical fascia (Gleeson 2016).

Masseter is quadrilateral in shape and is situated on the lateral surface of the ramus of the mandible. The muscle has three layers with different origin and insertion. The superficial layer of masseter has fibers in oblique direction (going downwards and backwards at 45°) originating from anterior 2/3rd of lower border of zygomatic arch and adjoining zygomatic process of maxilla. The insertion is at lower and posterior part of lateral surface of ramus of the mandible. The middle layer originates from the deep surface of anterior 2/3rd and lower border of posterior 1/3rd of zygomatic arch, and inserts at the middle of ramus of the mandible. The third layer, also called as the deep layer originates

from deep surface of zygomatic arch and inserts on the upper and anterior part of lateral surface of ramus of the mandible including the coronoid process (Sinnatamby 2011) (Fig. 1. Shows origin and insertion of superficial and deep fibers of the masseter muscle.).

The middle and deep layers cross the superficial layer in “X” – like manner forming a cruciate muscle (Wigley 2016). Intramuscular tendinous septa in superficial layer are responsible for the ridges on the surface of the ramus.

Relations of Masseter

Masseter has got two surfaces and two borders/margins.

- 1. Surfaces – Superficial and deep
- 2. Borders – Anterior and posterior

The structures related to the surfaces and borders are mentioned in Table 1 (Gleeson 2016).

Masseter Muscle, Fig. 1 Different layers of masseter muscle

Masseter Muscle, Table 1 Structures in relation to masseter muscle

| Superficial                                             | Deep                                                   | Anterior margin        | Posterior margin |

## Vascular Supply of Masseter

The vessels supplying the masseter muscle are:

1. Masseteric branch from the pterygoid part of maxillary artery
2. Masseteric branch from facial artery
3. Transverse facial branch of the superficial temporal artery

The masseteric artery accompanies the masseteric nerve as it passes behind the tendon of temporalis through the mandibular notch to enter the deep surface of masseter. The masseteric artery anastomoses with the masseteric branches of the facial artery and with the transverse facial branch of the superficial temporal artery. It also supplies the temporomandibular joint via its branch (Gleeson 2016).

## Nerve Supply of Masseter

The muscles of mastication develop from the first pharyngeal arch and hence are supplied by the nerve to this arch, the mandibular nerve. Specifically, the masseteric branch of the anterior trunk of the mandibular nerve supplies the masseteric muscle. The nerve enters the deep surface of the masseter by passing through the mandibular notch, immediately anterior to the capsule of the temporomandibular joint (gives articular branches to the joint, following the Hilton law) (Koshi 2018).

## Action of Masseter

1. Masseter elevates the mandible and clenches the teeth.
2. Its superficial fibers help to protract the mandible.
3. Acting alternately, the two muscles (right and left) move the chin from side to side, producing a grinding movement of the teeth.

The combined jaw closing action of masseter and temporalis pulls the condyle backwards,

as the pull of temporalis is greater than the associated forward pull of (superficial) masseter. The backward pull of the mandibular condyle is prevented by the simultaneous contraction of the upper head of lateral pterygoid, which stabilizes the condylar head against the articular eminence during closure, particularly during biting and mastication.

A pterygo-masseteric sling is formed by the masseter and medial pterygoid together to support the angle of the mandible. The robust attachments of these two muscles resists the surgical lengthening of the ramus (Evans 2016).

## Applied Anatomy

1. **Submasseteric space infections:** A series of spaces between the lateral surface of the ramus of the mandible and masseter, which are formed due to multiple insertions of fibers of masseter on the lateral surface of the ramus. Sporadically, infection around the mandibular third molar tooth tracks backwards and lateral to the mandibular ramus; pus localizes deep to the attachment of masseter in the submasseteric tissue space. Such an abscess produces negligible swelling but is accompanied by profound muscle spasm and severe limitation to opening of jaw (a clinical condition known as trismus) (Sinnatamby 2011).
2. **Palpable pulses:** Facial artery pulsation can be palpated anterior to masseter muscle on the lower border of mandible and on the face approximately 1 cm lateral to the angle of the mouth (Wineski 2019).
3. **Jaw jerk reflex or Masseter reflex (Fig. 2):** A dynamic stretch reflex is used to test the status of a patient's trigeminal nerve (C.N. V), as it regulates both the sensory and motor aspects of this reflex. It also helps in distinguishing an upper cervical cord compression from lesions occurring above foramen magnum.

**Procedure:** The mandible or lower jaw is tapped at a downward angle just below the lips at the chin while the mouth is held slightly open.

**Masseter Muscle,****Fig. 2** Pathway for jaw jerk reflex

**In response**, the masseter muscles will jerk the mandible upwards.

**Interpretation of the response** – Normally, this reflex is absent or very slight. However, in individuals with upper motor neuron lesions, the jaw jerk reflex can be quite pronounced.

**Reflex pathway:** it is a monosynaptic pathway where a tap on the chin below the lower lip activates muscle spindle afferents, which travel via the mandibular division of the trigeminal nerve to the brain stem. The cell bodies of these primary afferent neurones are located in the mesencephalic trigeminal nucleus. Collaterals project monosynaptically to the motor nucleus of the trigeminal nerve in the pons. Motor axons arising in the nucleus travel via the mandibular nerve to innervate the muscles that act on the temporomandibular joint and closes the jaw (Gleeson 2016).

4. **Spasm of masseter:** When in spasm, masseter holds the head of the mandible tightly against the articular tubercle of zygomatic arch causing anterior dislocation of temporomandibular joint. To perform the reduction of the joint back into the fossa, pressure is applied first downward and then backward on the mandibular molar teeth. The downward pressure helps in overcoming the spasm of the masseter and the backward force pushes the head back into the fossa by overcoming the spasm of the lateral pterygoid muscles (Sinnatamby 2011).
5. **Palpation of masseter:** Anterior border of the masseter is made prominent and palpable by

clenching the jaw (Charalampidou et al. 2008). This procedure is also used to test the integrity of trigeminal nerve (C. N. V) (Wineski 2019).

### Introduction

The matching-to-sample task is widely used in behavioral neuroscience and comparative cognition as a means of examining the underpinnings of working memory and testing a variety of cognitive processes. The most common version of the task is delayed matching-to-sample (DMS). On a typical DMS trial, following an intertrial interval, a subject is presented with a sample stimulus, followed by a delay period in which the sample is turned off (see Fig. 1a). After the delay, two

comparison stimuli appear, and the subject is required to select the stimulus that matched the sample stimulus they saw before the delay. If the chosen comparison stimulus is what had appeared as the sample stimulus then the subject is rewarded (Fig. 1a, left panel). If the subject chooses the comparison stimulus that is different to what had appeared as the sample stimulus they are not rewarded (Fig. 1a, right panel), and may be punished with a time-out from playing the task. Following either reward or punishment is the intertrial interval, signalling the start of the next trial. An animal may complete dozens of such trials in a daily session.

Konorski (1959) first proposed the matching-to-sample method as a means of investigating working memory in nonhuman animals, arguing that working memory was composed of a dynamic memory trace, and that previous methods did not sufficiently test this type of memory. Instead, previous methods of testing nonhuman animals could be easily solved without actively remembering information. For example, take the case where an animal is shown a sequence of three stimuli and is trained to respond if the sequence is different from the previous sequence. Rather than evaluating the position of each individual stimulus in the current sequence against its position in the previous sequence, it is possible to solve this task by only looking at whether the first or last items are the same across the two sequences. That is, an animal could solve these kinds of tasks by using other cues, or simpler forms of memory, than actual working memory. To examine true working memory, Konorski (1959) proposed that pairs of stimuli from the same modality should be presented one after the other, and that in order to be rewarded, the animal should respond when the stimuli match (go response). If the stimuli do not match, then the animal should withhold responding (no-go response). It is from Konorski's (1959) go/no-go paradigm that the matching-to-sample procedure evolved.

The first use of the matching-to-sample method with animals was by Blough (1959). While the method Konorski (1959) created displayed the sample and comparison stimuli one at a time,

**Matching-to-Sample: Comparative Overview, Fig. 1** An example of a trial from a (a) basic DMS task and a (b) conditional DMS task. For the basic DMS task, in order to be rewarded, the animal must select the comparison stimulus that is the same as the sample stimulus they saw just before the delay period. Note that the animal in the left panel makes a correct response, whereas in the right panel it makes an incorrect response. For the conditional DMS task, in order to be rewarded, the animal must select the comparison stimulus that is associated with the sample stimulus they saw just before the delay period. For the

example shown, the animal is trained to respond to the red comparison stimulus if the triangle served as the sample stimulus, and the green comparison stimulus if the sample stimulus was a line. Note that the animal in the left panel makes an incorrect response, whereas in the right panel, it makes a correct response. For both the basic and conditional DMS tasks, within a session the two sample stimuli would appear an equal number of times and would be followed by an equal number of presentations in which red would appear on the left and green on the right, as well as green on the left and red on the right

Blough (1959) displayed a sample stimulus followed by two simultaneously-presented comparison stimuli. Four pigeons were trained with light stimuli that were either flickering or steady. On each trial, pigeons were presented with one of these stimuli as the sample stimulus, followed by a delay. After the delay, both a flickering light and a steady light were presented, and the pigeons had to peck the one that matched the sample they had seen. The delay length started at 0 s (no delay), and, if pigeons performed at a suitable level, was gradually increased to 10 s. Blough (1959) found that two of the birds were able to perform the task well even at the longer delays, while the other two birds did not progress to the longer (5 and 10 s) delays during the study. For the two birds who performed poorly at long delays, performance nevertheless appeared to be a function of delay length, displaying a classic forgetting curve as

observed in humans (White et al. 1996). However, the birds that performed well at the longer delays did not seem to “forget” and appeared to use other strategies for remembering the sample. Overall, Blough’s original use of the DMS paradigm demonstrated the task’s usefulness in assessing working memory with animal subjects, despite the fact that some animals seemed to adopt non-memorial strategies.

## Variations of the DMS Task

The most common form of the DMS task is similar to the one used by Blough (1959) with two simultaneously-presented comparison stimuli, and has been used with many different species such as primates (D’Amato et al. 1985a), birds (Johnston et al. 2017a, b), fish (Goldman and

Shapiro 1979), and even bees (Giurfa et al. 2001). The other form is the successive go/no-go form proposed by Konorski (1959), in which stimuli are presented sequentially and the animals are trained to respond in one way when the comparison stimulus matches the sample stimulus, and withhold responding when it does not match (Miller et al. 1996; Miyashita and Chang 1988).

Beyond these two basic forms, there are many other variations of the matching-to-sample procedure. In delayed nonmatching-to-sample (DNMS, also known as oddity-from-sample), animals must respond to the comparison stimulus that does not match the sample (Zentall and Hogan 1974). It is also possible to structure the matching task such that the sample and comparison stimuli bear no physical relationship to each other. For example, in a conditional DMS task (also known as symbolic DMS, or delayed paired associate task; DPA), the sample stimuli may be shapes and the comparison stimuli may be colors (Fig. 1b). On each trial, animals are presented with one of the sample stimuli, followed by a delay. After the delay, the comparison stimuli are presented, and the animal must choose the comparison stimulus that is mapped onto the sample they just saw. For example, take the case where the sample stimuli can be either a triangle or a line, and red and green are the comparison stimuli. When the animal sees the triangle as the sample stimulus, it must choose the red stimulus during the comparison period (Fig. 1b, left panel). On the other hand, if it sees the line as the sample stimulus, then it must choose the green comparison stimulus (Fig. 1b, right panel). Symbolic DMS/DPA tasks can use comparison stimuli either from the same modality as the sample stimuli (Rainer et al. 1999) or from another modality (Colombo and Gross 1994).

The number of stimuli that are used within a session can also vary depending on the type of DMS procedure. For example, a DMS task can use trial-repetitive stimuli, in which the same set of (most often two) stimuli are used for every trial in a session. Alternatively, a DMS task can use trial-unique stimuli, in which each trial has a unique set of stimuli (Mishkin and Delacour 1975). DMS performance with trial-unique stimuli is typically better than performance with trial-

repetitive stimuli because the levels of proactive interference are higher with trial-repetitive tasks. Essentially, the DMS task is a complex discrimination procedure in which the animal must determine which stimulus appeared most recently as the sample stimulus. In the trial-repetitive version of the task, with only two stimuli serving as sample stimuli, determining which comparison stimulus served as the sample most recently is a far more difficult task than in a trial-unique version, where the stimuli change on every trial (D'Amato 1973).

## Matching-to-Sample Tasks and Comparative Cognition

In a simultaneous matching-to-sample (SMS) task, the sample stimulus remains on when the comparison stimuli appear. One of the most common uses of the SMS tasks is to study whether animals possess a matching concept, that is, an understanding of the concepts of same and different. The method is relatively straightforward. An animal is trained on a SMS task with two stimuli, say red and green. All animals tested can acquire such a task, but the important question is: *What exactly has the animal learned?* The “behavioral” interpretation is that the animal has learned a set of stimulus-response rules such as “press the red comparison if red was the sample” and “press the green comparison if green was the sample” (Carter and Werner 1978). The alternative “cognitive” view is that the animal learns a matching concept such as “press the comparison that matches the sample” (Zentall and Hogan 1974). One can distinguish between these two views by delivering a transfer test whereby novel stimuli, such as a circle and a plus sign, are used. According to the behavioral interpretation, in which the rules were learned specifically with the training stimuli (red and green), an animal should do poorly with the novel stimuli. On the other hand, if the animal’s behavior was driven by a cognitive rule, then testing the animal with novel stimuli should pose no difficulty, since the learned rule “press the comparison that matches the sample” is independent of any stimulus. Although a

brief review could never capture the complexities of the numerous studies that have explored whether animals possess a matching concept, monkeys (D'Amato et al. 1985a), birds (Wright 1997), and even bees (Giurfa et al. 2001) all do well when presented with novel stimuli.

Another use of the SMS task comes in studies investigating whether animals have the capacity for transitivity. For example, if  $A > B$  and  $B > C$ , we conclude that  $A$  must be greater than  $C$ . Can animals perform such logical operations? D'Amato, Salmon, Loukas, and Tomie (1985b) used an SMS task and trained animals on a first SMS relation with  $A$  and  $B$  as sample stimuli mapped onto  $C$  and  $D$  as comparison stimuli, such that when  $A$  was the sample stimulus, the correct comparison choice was  $C$ , and when  $B$  was the sample stimulus, the correct comparison choice was  $D$ . Once this first relation was learned, the animals then learned a second relation whereby the comparison stimuli of the first relation,  $C$  and  $D$ , became the sample stimuli of the second relation.  $C$  and  $D$  were then mapped onto a new set of comparison stimuli,  $E$  and  $F$ . Once the second relation was learned, the animals were tested for transitivity by using the sample stimuli of the first relation ( $A$  and  $B$ ) and the comparison stimuli of the second relation ( $E$  and  $F$ ). Although the animals had never experienced these pairings, the monkeys in the study fared quite well in that they selected  $E$  if  $A$  had appeared as the sample, and  $F$  if  $B$  had appeared as the sample. Such an outcome implies an underlying transitive relation guiding the monkeys' behavior.

The matching concept and transitivity are just two of the many uses of the versatile SMS/DMS procedure, which has also been used to investigate metacognition (Hampton 2001) and episodic memory (for an overview, see White et al. 1996; Griffiths et al. 1999). Another use of the DMS procedure has been to explore issues relating to whether animals engage in prospective processing, a form of mental time travel. Take the case of a standard DMS task that uses red and green stimuli. During the delay period, does the animal engage in retrospective processing and remember what it saw as the sample stimulus, or does it engage in prospective processing and

remember which stimulus it should press as the comparison stimulus to get a reward? Naturally, in the standard DMS task where the sample stimuli are the same as the comparison stimuli, it is not possible to untangle these two options. For example, if red was the sample stimulus, then a retrospective processing account (remembering the sample) would mean that an animal remembers "red," but a prospective processing account (remembering the correct comparison stimulus) would also mean that the animal remembers "red." One can get around this problem by using conditional DMS tasks where the sample stimuli are mapped onto physically different comparison stimuli, much like in the case of the previously described transitivity study (see also Fig. 1b). For example, take the case of Fig. 1b where the sample stimuli are a triangle and a line that are mapped onto the red and green comparison stimuli, respectively. Let us assume a trial where the animal sees the triangle as the sample stimulus. If the animal is retrospectively processing, then it must be remembering "triangle," whereas if it is prospectively processing, it must be remembering "red." Using such a conditional DMS task, with either physically different visual sample and visual comparison stimuli, or auditory samples and visual comparison stimuli, it is possible to show that animals do indeed engage in prospective processing (for an overview of animal studies showing prospective processing, see Colombo et al. 2017).

## Matching-to-Sample Tasks and Behavioral Neuroscience

The DMS task has been a cornerstone task used in almost all studies that have examined the neural basis of memory, from early lesions studies, to later electrophysiological studies. The DMS task was used extensively throughout the 1980s and 1990s to explore the role of the hippocampus in learning and memory (for a review, see Colombo and Broadbent 2000). The advantage of the DMS task is that by using delays of various lengths, one can simultaneously explore the impact of a lesion on memory, as well as basic discriminatory

abilities. For example, if a structure was involved in memory, then one might expect the impairment to be minimal at a short delay where the memory load is minimal, and increase for longer delays, as memory load becomes more noticeable. Such might have been the case with damage to the hippocampus (see Colombo and Broadbent 2000, and references therein). Alternatively, damage that encroaches on the visual system will cause perceptual impairments that manifest as impairments at both the short and long delay (see Colombo and Broadbent 2000, and references therein).

Electrophysiological studies of memory have also relied heavily on the DMS procedure. One of the most common ways to explore the neural mechanisms of memory is to study what is known as delay activity. Fuster and Jervey (1981, 1982) were the first to notice delay activity, initially in the prefrontal cortex (PFC), and later in the inferior temporal (IT) cortex. Fuster and colleagues noticed that some cells in PFC and IT cortex continued to fire during the delay period, a time in which the animal is presumably remembering information either about the sample stimulus or the anticipated correct comparison stimulus. Miyashita and Chang (1988) argued that delay activity represents a neural correlate of memory. Evidence that an animal's performance on the DMS tasks is correlated with aspects of delay activity seems to lend support to this notion (see also Colombo and Gross 1994). Delay activity has now been identified in many regions of the brain across many different species including rats (Sakurai 1990) and birds (Johnston et al. 2017a, b).

The DMS task has been used to explore the possible role of delay activity in coding aspects of behavior other than memory for the sample stimulus. For example, both studies with monkeys (Rainer et al. 1999) and studies with crows (Moll and Nieder 2015; Veit et al. 2015) have shown that delay activity may represent a neural code of a prospective stimulus. Additionally, studies of categorization (Freedman et al. 2001), numerosity (Ditz and Nieder 2016), and abstract rule learning (Veit and Nieder 2013) have all utilized versions of the DMS task to understand what information animals are processing during a delay period.

## Conclusions

Since its conception by Konorski in 1959, the DMS task has been widely used in comparative cognition studies exploring the cognitive abilities of animals, and neuroscience studies exploring the neural basis of learning and memory, both in a variety of different animals. In fact, it is its ease of use across so many different species that makes matching-to-sample procedures such powerful tools.

## Mate Guarding

Gisela Sobral

Departamento de Reprodução Animal, Faculdade de Medicina Veterinária e Zootecnia, Universidade de São Paulo, São Paulo, Brazil

## Synonyms

Mate guard

## Antonyms

Mate searching

## Definition

To guard a mate, or to prevent a mate from (re) mating with other mates/partners; to stay with partner longer than the time required for mating.

## Evolutionary Context

Although mate guarding mechanism has evolved to ensure paternity of the one guarding, evolution should also confer some selective advantage to the guarded partner. Before understanding it fully, it is important to understand the reproductive context in which it is included.

Mate guarding can be observed in both sexes, but is more frequently reported among males within a variety of species. This sex bias is possibly a response or consequence to male gamete evolution in Animal Kingdom. Animal male gametes ARE tiny and numerous tiny and numerous, outnumbering the female's by many folds, which are large and rare. These different morphologies

between gametes (anisogamy) oppose to gametes of equal sizes (isogamy), a much rarer condition but believed to occur in the first sexual organisms (Bell 1982).

Anisogamy is also thought to be the origin of asymmetry in gender roles. According to Trivers (1972), the gender that invests less in the offspring should be the competitive one, and the one who invests more should be choosy. Since the actual sperm contribution to the zygote survival is nearly absent, males are more likely to be the sex that invests less in offspring as they provide little more than just semen. Conversely, females produce fewer gametes and they devote a great deal of resource on them, so that zygote survival is highly dependent on her. Thus, female contribution to the next generation is directly related to the number of eggs released and/or matured at the time of ovulation, while male contribution to the next generation is much more variable (Bateman 1948). Since female gametes are a scarcer resource, almost every male must compete for an egg at least once in their lifetime. If females are rare, competition will be even stronger. There must be competition in order to mate guarding to occur.

High gamete productivity yields an advantage through sperm competition and anisogamy sets up the conditions since the highly abundant male gametes will compete to fertilize the limited female gametes (Bjork and Pitnick 2006). Interestingly, mate guarding males are predicted to produce less sperm than males that are always in sperm competition. However, it is whether not clear if sperm reduction is a cause or consequence from mate guarding.

The general scenario that mate guarding should occur as means of high gamete competition is broadly accepted, but the lack of body literature regarding its evolution possibly indicates that it has multiple origins. Among insects, Parker (1970) has shown a neat evolutionary trend of internal fertilization to external fertilization. The evolution of internal reproduction without copulation, observed among terrestrial insects, but also in marine animals (such as crustaceans), provides a shorter fertilization time by placing the protected sperm as closer to the eggs as possible. Internal reproduction can be dissociated from

copulation when the sperm is not free, but encapsulated somehow. This means that males will spend more energy in producing capsules and spend more time in placing the capsules along the females' path. Consequently, these males are slightly choosier due to its increase in gamete investment. Yet, the male does not need to be present for the fertilization to happen. On the other hand, females produce hundreds to thousands of eggs and there is a delay between sperm placement and the actual eggs' fertilization, with plenty of opportunity for multiple matings. Therefore, there is an absent male that has dedicated time and energy to a single female, and the possibility of multiple males to copulate with this same female, handicapping all the first male's effort. At this point, mate guarding will boost the male's outcome and fitness if he manages to protect the female and, consequently, his sperm.

Still following Parker (1970), further selective pressures brought internal fertilization associated with copulation. The male introduces the sperm (usually free) even closer to the female's eggs, inside her reproductive tract and, consequently, there is now the need for him to be present. This is probably one of the most familiar reproductive systems that possibly led to the evolution of a copulatory organ, such as the penis or phallum. Although this system bestows the sperm closer to the eggs, the negative consequence is that the male needs to spend even more time and energy with a single female. By reaping his chances to further mate with more females, he needs to assure that his sperm will not be replaced nor displaced by subsequent males, should a second mating occur. That is, if there is a high probability of losing fertilizations through sperm competition or if probability of finding another mate is low, such dedication may constitute time waste.

In insects, there is the "last male favoritism" and the male that mates last fertilizes more eggs than the previous one, while the female produces a fixed amount of eggs irrespective of how many matings she had. At this point, there will be two opposite evolutionary directions. At one end, the second male tries to displace as much sperm as possible from the first male (increased sperm competition), producing an even greater amount of

sperm to displace any possible previous sperm and still have plenty to fill storage organs (the spermatheca) with a single ejaculation in insects, such as the fly *Drosophila melanogaster*. At the other end, there is the first male that is able to avoid or reduce sperm competition by preventing a second male to mate (increased mate guard). Extended copulation is a common form of mate guarding. In dung fly *Scatophaga stercoraria*, if copula duration is prolonged, there is an increase in fertilization rates by the male. Parker (1970) emphasized that this strategy is disadvantageous in two ways, first the male will reduce the number of females mated and, secondly, there is a high chance of takeover from other males when attached the female.

No similar review has been done to other invertebrates nor vertebrates. However, most species (e.g., mammals) show polygamous breeding systems with a high male competition and mate guarding has been intensively studied in this group. Mate guarding among vertebrates is diverse in both type and duration. Duration is extremely variable and may start many days before conception and finish many weeks after it. When reaching the maximum time and energy expenditure in one female, it is believed that this have been a precursor of monogamy. Monogamy, in turn, might be serial (temporary, during a single breeding season) or last for a lifetime (more frequent among birds). The wide variety of forms include pre- or postcopulatory; physical, chemical, behavioral; solo or cooperative. Each will be presented separately, followed by the taxonomic examples observed in the Animal Kingdom.

## Female Mate Guarding

The female mate guarding hypothesis is much rarer and was proposed to explain the frequent copulation observed in birds (Petrie 1992). Females may copulate regularly (even outside the fertile period) to reduce the likelihood of her partner to mate with other females. She may accomplish her goal by reducing his sperm stocks and depleting his energy reserves. In birds, copula is important in establishing a pair bond and by

reducing the chance of her partner to mate with other females, she is also reducing the chances of another female to establish a pair bond with him. Mate loss is particularly important if the male is of high quality and low quality ones will be less solicited, as seen in wild American kestrel *Falco sparverius*. Another important feature in birds that might have helped the evolution of such tactics is that many species are monogamous, with biparental care. Thus, females will suffer a cost from her partner having multiple mates, reducing his care toward their young. This form of mate guarding has not been described for any other group besides birds.

### Cooperative Mate Guarding

Another exception among mate guarding types. Solo mate guarding is the rule while its cooperative counterpart is the exception. Therefore, solo mate guarding will not be presented in a singular session but will be addressed throughout sessions.

Within some species, males form coalitions or alliances that may coercively maintain consortships (or herding) with females, sometimes considered as cooperative mate guarding. Both chimpanzees *Pan troglodytes* and bottlenose dolphins *Tursiops truncatus* males mate guard in alliance with other males. In the case of the bottlenose dolphins, this is possibly because of the high energetic cost of guarding highly mobile female (see “[Mammals](#)” section below). However, both species aggressively herd females and consortships are longer than the receptive period because competition is high when female is the most attractive (e.g., during the fertile period). If the alliance waits for maximal attractiveness before start consorting, other males (or coalitions) may confiscate her.

### Precopulatory Mate Guarding

Precopulatory mate guarding may have evolved if female receptivity is low or if mate searching costs are higher than the cost of guarding. Precopulatory mate guarding is a very common

form and usually includes following up a female until she becomes receptive. Within the mechanical version of precopulatory mate guarding, the male adopts a what-so-called passive phase, when the male stays attached to the female and physically impedes other males to reach her. Many insects, such as beetles’ families, show this behavior. A not so passive phase consists of competing aggressively with other males and, thus, precopulatory mate guarding may overlap with male-male competition.

The behavioral version of precopulatory mate guarding includes a looser phase, although Parker (1970) still considers it as “passive,” as observed in the male termite, which follows closely the female that is in search of an adequate nest site. Some Odonata show this behavior, with females ovipositing on submerged vegetation while the male partner attacks any approaching male. Some males even guard more than one female, placing the second one closer to the first and guarding both.

Territory defense is a possible version of extended precopulatory noncontacting guarding as the males protect likely areas in which a female will enter. A similar strategy is present in harem defenders ungulates. Amid these hoofed animals, males are territorial and females are gregarious, and a male will defend females until they become receptive to his attempts.

### Postcopulatory Mate Guarding

This form is the most widely studied and observed. In many taxons, postcopulatory mate guarding is so long that male presence and protection against other males may function as parental care and protection of the brood.

Tactics are numerous. Chemical agents present in seminal fluid may induce unreceptivity in Diptera female, while many mammals present copulatory plugs that function as “chastity belts.” Copulatory plugs are chemical constituents that cause seminal coagulation immediately after ejaculation. Although it is mainly associated with further mating impedance, they may also function to minimize sperm loss and promote their survival

within the alkaline environment of the vagina. Harvestmen and some dipterans have developed anatomical adaptations such as spined femora or adapted antennae to grasp the female during copulation. Acrinoid males emit sounds against searching males. Cerambycids males produce disturbance stridulation as a reaction to attack from other males.

Parker (1970) assigned this version of mate guarding to the high density of males. In dung flies *Scatophaga stercoraria*, the male remains close to the female while she oviposits. If he fails, other males might take over and will copulate with her until the moment she has laid her last egg. The familiar “tandem position” observed in many dragonfly species of Odonata occurs after mating and while the female is ovipositing. Like the dung fly, takeovers have been observed if the male is not in contact with the female. Nonetheless, protection during oviposition is also positive to the female as she will be protected during oviposition and will avoid attacks of rival males.

Prolonged postcopulatory mate guarding can be costly for males as increased copula duration is associated with reduction of food reserves. In locusts, males can reach nearby food while mounting or protecting the female, and mature males have greater fat reserves, guarding for longer periods. Crickets are also among the taxons that present prolonged postcopulatory behaviors. In this case, the male keeps the pair immobile and, thus, he prevents her from removing the spermatophore, ascertaining multiple copulation with the same female. In Hemipterans, passive phases are linked with parental care. When the female has laid all her eggs and left, the male continues caring for the laid eggs, even after they have hatched. However, other females may visit the egg mass and add their own, increasing fertilization rates for the brooding male.

## Mate Guarding and Sexual Conflict

Although mate guarding has obvious advantages for males, females may also benefit from guarding. Firstly, they may be protected from harassment of other males (as seen in colonial breeders birds, where females may be followed

by up to six males). Secondly, they may be protected from potential predators and, thus, females can focus on foraging and increase their foraging success. Thirdly, if guarding results from competition, females may benefit from the increased fitness from high quality males.

However, sexual conflict stands for opposing interests in mating between sexes. Male interests may contradict the female’s concerning feeding or predation avoidance. Females cannot be regarded as inert and passive beings. Therefore, their collaboration plays an important role in the success of mate guarding. If she is not willing to mate with the one guarding her, she may actively look for other mates and, thus, configure extra-pair copulation if in a monogamous mating system (see “► [Extra-Pair Copulation](#)” entry).

Female isopods *Idotea baltica* resist attempting males by many behavioral mechanisms, such as kicking and bending their bodies for days. Larger males, on the other hand, were better in overcoming their resistance. The lesser waxmoth *Achroia grisella* shows an extended mating time as a form of prefertilization mate guarding, but it also decreases mobility and renders the pair more vulnerable to predation. This species is short lived and nonfeeding as adults, so the whole reproductive bout needs to be fast and functional. Female Seychelles warbler *Acrocephalus sechellensis* scape their mates’ guard to seek partners either for indirect genetic gains or for direct phenotypic gains. Unattractive male blue tits *Cyanistes caeruleus* will guard a female more intensively and she will take advantage of his guarding as she will spend less time fending off against intruding males while she will copulate with a higher quality male.

Prolonged guarding increased the likelihood of aggressive encounters with unpaired males (and possible injuries) and reduced feeding opportunities for the final molt in blue crabs. However, this species copulates only once and, if the female does not collaborate, she might miss this mating opportunity. Females have some control on when the mate guarding begins. Pairing was easier with late pre-molted females suggesting that those females are seeking for mates, while early pre-molted females avoid being guarded.

Summarizing when a male guards and the female copulates with him, it is not possible to deduce that the female prefers this male or if she was coerced by him or if she has no other choice as he chases other males away. Connor et al. (1996) hypothesized that extended cycling period is a counterstrategy to herding by males. Females will reduce alliance monopolization by increasing the number of times they cycle.

## Mate Guarding and Hormones

Sexual and aggressive behavior are usually androgen dependent in males. Aggressiveness as means of mate-guarding behavior should, then, be affected by alteration in circulating testosterone levels in males and has been observed to do so in birds and mammals. Testosterone is also associated with the development of male secondary sexual characteristics, leading them to have bigger bodies and/or larger weaponry, brighter colors, etc. enhancing his guarding abilities.

A study with male barn swallows *Hirundo rustica* (Saino and Møller 1995) showed that circulating testosterone levels were positively correlated with the intensity of mate guarding. Thus, if mate guarding is dependent on testosterone levels, then additional costs of mate guarding arise because of immunosuppressive effects of high testosterone levels. Everything else being equal, males with higher testosterone concentrations are more likely to pay the costs of time, energy, and immunosuppression caused by this hormone.

Pheromones are also decisive for mate guarding. The blue crab *Callinectes sapidus* female produces a urinary-origin pheromone released several days prior to molting that signalize to males that her molting approaches.

## Mate Guarding and The Evolution of Male Alternative Strategy

Size usually defines which males win contests and competitions. Large males consistently guard females better and for longer periods. Smaller males, on the other hand, will not be capable of

keeping this duty for long. The smaller male will be outcompeted and displaced by larger males. Therefore, the evolution of alternative “types” (named as strategies) of males is a counterstrategy to win competitions against larger males by other means. While LARGER males are able to guard females and other resources, SMALLER ONES rely on “sneaky” matings. There can also be an intermediate male, presenting a mixed and plastic strategy, playing in either one side or the other, depending on the situation and depending on the male that he is competing with. This is common among cuttlefishes, lizards, and many bone fish.

In lizards, such as *Psammodromus algirus*, body size is age dependent and, henceforth, old males are the ones who guard, while young males are small and ill-equipped to guard females and seek forced copulation.

## Mate Guarding Examples Among Taxa

### Asexual Reproductive Animals

Animals of obligate asexual reproduction (vegetative or parthenogenetic) are rare, less than 1,000. In some animals, such as bdelloid rotifers from Phylum Rotifera, sexual reproduction has never been recorded. Mate guarding has not been described for any of these animals.

### Hermaphrodites and Aquatic/Sea Animals

Michiels (1998) presented a table showing that many phyla have at least one hermaphroditic representative. Among hermaphrodite individuals, selection on male traits is not independent from the females as they coexist in the same individual. Additionally, gonochorists (just one sex in one individual organism) differ from hermaphrodites in mating opportunities. Whereas in gonochorists females limit mating opportunities, in hermaphrodites donor individuals (equivalent to males) are limited by its own capacity to inseminate partners and receiving is costly (e.g., parasite transmission), leading researchers to classify donors as choosy instead. One nearly universal aspect among hermaphroditic animals is their low density. Thus, partners are too rare to be selective and promiscuous matings in outcrossing

hermaphrodites are likely to occur. Michiels (1998) also states that the physical removal of sperm from sperm storage organs is absent from hermaphrodites, although part of autosperm and allosperm is likely to be digested. Adding, for instance, the reluctant donation to the low population densities, hermaphrodites may not benefit from sperm exclusivity and mate guarding. There seems to be nothing that a partner can offer that the receiver does not already have. In species where multiple individuals participate in mating, on the arrival of a third individual, previous partners may start competing for the new one, instead of protecting each other.

Phyla in which hermaphroditism is almost ubiquitous comprise those mainly of aquatic and marine environments (sponges, corals, bryozoans, ctenophorans) with an ancestral condition of mating behavior. Among these sessile species, adults release gametes into the external medium (called “spawners”), fertilization can be either external (e.g., some corals and ctenophorans) or internal (e.g., sponges and bryozoans), and these individuals mate assortatively (matching phenotypes, as in, larger individuals will prefer to mate with a larger partner). Sea turbulence diffuses gametes concentration to a point that their encounter is rare. Competition among gametes is furious, and there has been no report on mate guarding for such species. Since in marine environment chemical substances play an important role in communication, we have no reason to think that chemical mate guarding should not occur.

Some non-sessile animals, such as the slug *Ariolimax columbianus*, frequently lose their penis during copulation and could be interpreted as means of reducing mating opportunities. Similarly, the flatworm *Dugesia gonocephala* remains in copula for up to 10 h, almost 5 h after sperm transfer is completed. Mate Guarding has not been described for them either.

## Invertebrates

### Aranea

Arachnid females are usually larger than males. Large and heavy females are more fecund, carrying a greater number of eggs and, thus, are of

greater values for males than smaller light females. During breeding season, male *Metellina segmentata* guard female webs for several days prior to mating, which occurs when a pray of suitable size is trapped in the guarded web. It is important that the male is able to gather information on the resident female receptivity so that he does not waste time guarding immature females. Assessment may be tactile, chemical signaling, and web vibration.

### Crustaceans

Regarding other invertebrates, mate guarding is also common among Crustaceans. In this group, female is receptive during a brief period after molting, a period in which carapace is soft and she is vulnerable to predators and injuries from struggles. Thus, precopulatory mate guarding has evolved as males compete intensively for these scarce females and they, in turn, benefit from protection during this delicate stage. The precopulatory mate guard is energetically costly since males use energy reserve to carry females or when the pair spends time in a low-quality refuge during this phase. Since males reduce drastically their feeding rate while precopula mate guarding, a key point is that males are able to detect the molt stage of females accordingly.

**Copepoda** Copepods also have copulation restricted to a very brief period, soon after the female molts. Mate guarding behavior includes close physical association with clasping or carrying to defend females. This is reflected in the evolution of special characteristics that helps them sequestering females, such as increased body size (at least the same size of the female counterpart), enlarged cheliped weapon, and aggressive behavior toward other males.

As reported many times previously, guarding females longer than the time needed represents a significant investment that could be used searching for receptive females. Should the probability of encountering receptive females be low and males mate only once in their lifetime, it would be advantageous for males to guard unmated and even immature females until their terminal stage. Pheromones play an important role

in mate seeking among copepods (shrimps, lobsters, crabs).

Mate guarding in copepods is defined as when males clasp to the females at terminal molting stage. The female reaches sexual maturity after the last copepodid stage, and one copulation seems to be sufficient for the complete fertilization of eggs. After she has finished molting, male clasping is classified as true copulatory behavior. However, some calanoid copepods remate during the gravid phase so that a greater egg mass is produced. In this case, female receptivity is less predictable since fertilization window is larger.

***Isopoda and Amphipoda*** In isopods and amphipods, there is an operational sex ratio bias toward males, reducing severely the mating opportunities per male. In extreme cases of very low female density, permanent mate guarding (or partner fidelity or even monogamy) will be selected for. Precopula mate guarding would not be adaptive if receptive females were numerous and encountering rates were extremely high. A model was proposed for crustaceans by Wickler and Seibt (1981), stating that if female inter-spawn interval was greater and 3–4 days (most crustaceans) and if a male meets up to two females a day, then precopulatory mate guarding is predicted. If encounter rate is higher, mate searching is favored.

***Decapoda*** Several species lack obvious traits that help mate guarding. *Heptacarpus* spp., *Palaemon* spp., and *Palaemonetes* spp. are all highly gregarious species with males smaller than females, not particularly aggressive and weakly armed. In *Palaemonetes pugio*, however, there was no support that mate guarding occurred as males did not exhibit either morphological or behavioral indicative. Despite the fact that there was an increase in male contacts with the molting female, it was too short (1 h before she molted) for Bauer and Abdalla (2001) to consider it as mate guarding. This conservatism was due to Ridley (1983) definition that premating guard needs to last more than 1 h. The former authors interpreted that this species was able to detect pre-spawning females only shortly before her molt.

Hermit crabs occupy empty gastropod shells, and there is individual difference in shell size preference based on past experience of shell availability. Thus, much of the studies with hermit crabs address their memory. Male hermit crabs *Pagurus middendorffii* can assess sex ratio and operational sex ratio (proportion of sexually mature males to inseminated females) in order to extend their mate guarding. Assessment can be through counting both the number of competitors and the number of receptive females or even by memorizing encounter frequencies. Small hermit *P. middendorffii* guarded females earlier than larger males, though the big ones could take over at any time in Wada et al. (1999) lab experiment, so that guarding was unserviceable.

### Cephalopoda

Cuttlefishes are all about number. Usually, population is male biased. They are spawners and form large aggregations in which the female lays 1 egg at a time, reaching up to 39 a day, while mating 17 times with 2 to 8 males a day. Guarding males account for 64% of matings and the remainder by extrapair males. Mate guarding behavior of cuttlefishes manifests in many ways. The large males hover above females or place themselves between the female and other males. If the female is under a rock, the guarding male stays at the entrance. Challengers draw agonistic displays and very rarely it escalates to physical combats. The guarding male is persistent, maintain pre- and postcopulatory guard, and, thus, it may occur last male precedence. Indeed, this long mate guarding does not translate into high fertilization success due to strong sperm competition and/or cryptic female choice.

Octopuses also present mate guarding, and different categories were classified based on its arm's reach, being either adjacent (male and female within arm's reach of each other) and temporary (not adjacent). Like cuttlefishes, size determines which males win contests. If a small male is guarding a female, it is very likely that he will not be able to do so. The large males usually displace the smaller ones.

## Insects

Insects perhaps show the widest array of mate guarding for two main reasons: (i) sperm longevity, allowing enough time for multiple males to compete for the eggs fertilization; (ii) mating occurs in conditions of high densities, where searching males fight for the possession of females, resulting in “gregarious mating.” Therefore, mate guarding has been observed and well studied in this group. One of the most common features among insects is that copulation duration is often longer than the required for transmission of full seminal fluids and sperm. The presence of the male’s genitalia acts as copulatory plugs and prevents other males from inseminating the female. The most commonly shared type of mate guarding in this group is the postcopulatory one and the last male to mate with a female fertilized the greatest proportion of eggs (last male precedence) is usually the norm among insects (see Alcock 1994).

**Lepidoptera** Butterflies and moths follow a well-known mating system, in which the female remains close to its emerging site, emits a long-distance chemical calling, while males search persistently those females by means of sensitivity to their pheromones. The lesser waxmoth *Achroia grisella* shows an extended mating time as a form of prefertilization mate guarding. Conversely, other moth species, such as *Pectinophora gossypiella*, males enter a refractory period, becoming sexual inactive for approximately 24 h after mating. This difference might result from the virtually absent cost of a second mating trial. Additionally, flying has a high energetic cost and, for such a short living creature, attempts to remate or stay in a refractory period and avoid flying is advantageous.

**Hemiptera** Prolonged postinsemination copulation is also common in Hemipterans species with dense aggregations where encounter probability among individuals is high and population is male biased. Additionally, in *Lygaeus equestris*, the last male to fertilize may sire up to 90% of the subsequent eggs.

Most species with prolonged insemination, such as the cotton stained *Dysdercus* sp., *Nezara viridula*, water striders *Gerris remiges* and *G. lateralis*, departs soon before oviposition. Water strider males ride passively on the back of the females after copulation and its function as mate guarding has been discussed over the years. Females may storage sperm up to 30 days and stay fertile up to 60. Hence, one or a few matings are sufficient for the complete fertilization of her eggs and multiple matings may have little benefits in terms of increased fertility. As for the males, the last one to mate will sire about 90% of the upcoming brood in many species from the *Gerris* genus (Arnqvist 1988). Additionally, since many water striders are polyandrous, there should be minor gains to the male in providing protection to the female and, instead, mate guarding serves mainly as paternity insurance.

However, in the soapberry bug *Jadera haematoloma*, male stays with the female even after she has laid her eggs, guarding her and eventually recopulating afterwards. Female soapberry bugs take 25 days (for single copulation) for complete sperm depletion. Paternity loss for females that copulated with multiple males accounted for 60%. Carroll (1991), however, considered as “enigmatic” that males guarded only during one oviposition, hypothesizing that the time taken to find another mate and guard her until oviposition must be greater than the time required for waiting the first female to produce another brood.

**Orthoptera** Crickets complete their copulation when the male transfer a spermatophore, a small sperm-containing ampulla that hangs outside the female’s body. Females usually dispose the spermatophore by consuming it and often do it before it has been emptied. Thus, one of the hypotheses for the evolution of postcopulatory mate guarding in crickets accounts for the prevention of early removal of spermatophore and presenting the female with a nutritious part of the spermatophore (the spermatophylax) so that she remains close and occupied. Another hypothesis is that while the male maintains close proximity to the female, he has enough time to produce an extra

spermatophore, allowing him to recopulate with the same female. The third hypothesis is that mate guarding functions to impend the approach of other males and reduce sperm competition. Mated females will mount intruder males and the thrusting actions may increase the risk of dislodging the previous' mate ampulla. Although it also prevents premature ampulla removal, unlike the first hypothesis, this one excludes other males approach rather than controlling the female.

Males initiate mate guarding immediately after copulation by maintaining close proximity to their mates through many tactics, such as standing right next to the female, frequently antennating the female, searching rapidly if she becomes unreachable, producing aggressive chirps upon movement from an intruder male, and physically attacking this intruder.

In decorated crickets *Gryllobates supplicans*, mate guarding did not prevent premature removal of the sperm ampulla. Yet, duration was positively correlated with the ampulla retention. However, males that manage to deflect courtship attempts of intruder males reduced the molting frequency of their mates and concomitantly reduced the risks of ampulla displacement.

## Vertebrates

### Fish

“Bone Fish” Females are almost universally correlated with fecundity and males engage in parental care. Most of the studies with fish thus relate mate guarding with the actual guard of the brood and nest. Therefore, much of the observed mate guarding is overlapped with parental care. Still, if mate guard is a strategy to increase paternity, deserted or unattended eggs are likely to die, becoming a waste of time and energy.

Among Amazonian cichlids, both parents rear the young, with the male being more assiduous than the female. However, Yamamoto et al. (1999) has emphasized that male-male aggression serves both offspring protection and territory protection. The latter, in turn, is elementary to partner acquisition and retention.

In Mediterranean wrasse *Symphodus ocellatus*, males may experience no sperm competition even with as many as 20 males vulturing nests. Three independent male mating strategy occur in this species, similar to the pattern observed in lizards: (i) larger males build nests (“nesting males”) and guard females, with lower production of sperm; (ii) intermediate-sized males (“satellite males”) does not guard and produce a similar amount of sperm as the nesting males, and iii) smaller males (“sneakers”) are incapable of guarding nests and are specialized in sperm competition with their increased gonad mass. Thus, males may switch strategies between allocating more resources to sperm competition or to mate guarding, depending on which conditions are worthwhile endeavor in each season. Satellite males decrease the number of sneaker males by joining their spawn and may allocate energy to mate guard. Sneakers, on the other hand, contribute significantly more to sperm as they are unable to guard against large nesting males or larger satellite males. Interestingly, both males and females of the monogamous butterflyfish *Elacatinus evelynae* are aggressive toward same sex intruders and are consistent with mate guarding by both sexes.

Several fish are sequentially hermaphroditic (individuals first functioning as one sex and then changing to the opposite sex). Sex change control is influenced by the dominant individual that aggressively overt others. Although there are other exogenous and endogenous factors that control sex change in fish, social control has been observed in anemone fish *Amphiprion*, in which females control the production of other females by means of dominant aggression over males. Some species within this genus such as the skunk clownfish *A. akallopisos* are monogamous in pairs or in groups, of which the largest individual is always a female that is dominant over other group members. The largest male prevents other males from spawning, maintaining the monogamy of the group. The removal of the dominant female leads to one subordinate male (beta) taking over the alpha position and change his sex. Such system may have evolved due to low density population of host anemones.

**“Cartilaginous Fish”** Male sand tiger sharks *Carcharias taurus* have been reported to present mate guarding behavior in captivity, with the usual scenario of the dominant male physically excluding rivals from females until he has copulated with them.

### Amphibians

Most of amphibians are polyandrous with sequential polyandry. Sequential polyandry is when the female mates with one male and produces a clutch of eggs of this one male, then leaves the eggs either being incubated by him or unprotected, while moving on to another male in a different nesting place. In the most common anuran mating behavior, the male stays mechanically attached to the females (amplexus) until she has laid the eggs, eventually releasing his own sperm. Some males even developed nuptial pads on their forearms, a morphological adaptation to ensure a tight grip on the female. Females are usually larger than males and similar to what has been observed in spiders; larger females produce larger clutches of smaller ova. Hence, these larger females are also of greater value for males.

The amplexus may be considered as mate guarding behavior as unpaired males try to access females by dislodging amplexant males. Attempts of multiple males to participate and mate with a single female occur frequently. In many explosive breeding ranids, availability of female is brief due to its abbreviated breeding seasons. Among these species, prolonged amplexus is considered as a mate guarding mechanism. The term “mate guarding monogamy” has been applied for frog species such as *Atelopus* sp., in which male remains amplexed to the female as long as 32 days prior to the egg release. Male-female duetting of the South African clawed frog *Xenopus laevis* serves, among other functions, as pair bond maintenance, territory defense, and acoustic mate guarding.

### “Reptilians”

Long-term mate guarding is apparently rare in ectothermic vertebrates (usually referred as “cold-blooded” vertebrates), consisting of periods shorter than 24 h.

The largest *Ameiva* males attain the right to guard females, when the male fights with other males and the winner stays in close proximity to her. The male guards the female and copulates with her just before she returns to the burrow at the end of the day, though he carries on guarding for a while before he returns to his burrow. When she emerges the next day, the cycle repeats, with guarding lasting until the end of her receptive period. In a population from the Lesser Antilles, females spend more time foraging while being guarded by males, suggesting that mate guard also serves as extra protection for her, expelling males but also alerting for potential predators. While *Ameiva plei* is a nonterritorial species and, thus, males neither control nor monopolize resources, old *Psammudromus algirus* males are territorial. These elderly males court females for long periods, copulate with them, and guard them afterwards.

Side-blotched lizards *Uta stansburiana* present three male morphotypes. The ultradominant males are orange throated, sneaker males are yellow throated, and intermediate dominant males are blue throated. The ultradominant males have naturally high plasmatic testosterone levels. Conversely, yellow-throated males present lower plasma levels and mimic females in order to avoid agonistic encounters with these ultradominant males. They also do not defend territories but have large home ranges that include many orange males, copulating with some females that the ultradominant did not manage to monopolize. Yellow-throated may transform into blue throated individual within the dearth of territory defenders. Intermediate blue-throated males have intermediate testosterone levels and bear modest territories, efficiently protecting fewer females from the sneaker yellow males. They are, though, incapable of winning contests against the ultradominant orange males. Their relative reproductive success may change throughout time and change morphotype frequency in populations.

In the snow skink *Niveoscincus microlepidotus*, males and females form pairs, males are highly aggressive toward other approaching males, and therefore, it is considered as a type of

mate guarding. It is unclear if males guard reproductive females that they have already mated or if they guard females that are in the imminence of birth giving and becoming receptive shortly (within a few weeks). They use their chemosensory ability to recognize mates and prolong pair formation.

### Mammals

Poligamy is almost ubiquitous to mammals. More specifically, polygyny is the prevailing mating system, where male mammals control access to many females. Hence, guarding male is a common scenario within this group of animals.

**Monotremata** Echidnas hibernate and males emerge from hibernation before females. As soon as 30 days after the end of hibernation, males are ready to mate. Males remain reproductive active for about 60 days but stay with females up to 7 days. There have been males that stayed in close proximity with up to four females. It appears that males are promiscuous rovers that guard promiscuous females before and after mating. In Tasmanian echidnas, some males were found mating repeatedly with hibernating females thus insuring high probability of successful paternity since females appear to be induced ovulators (copulation triggers ovulation).

**Marsupialia** Many Australian marsupials are semelparous (breed once in their lifetime and then die). Mate guarding thus presents an extra energy load to this costly reproductive strategy. The brown and the agile antechinus, *Antechinus stuartii* and *A. agilis*, are semelparous marsupials and present extended copulation periods that are considered as a form of mate guarding. This tactic, although not effective in obtaining exclusive paternity, reduces sperm competition and/or displacement.

Among platypuses *Ornithorhynchus anatinus*, females seems to actively control encounters with possible mates. The female may alter their activity patterns until she becomes receptive and males had little capacity to control courtship, and, therefore, unable to mate guard her (Thomas et al. 2018).

**Small Mammals – Rodentia, Chiroptera, and Lagomorpha** Rodents have variable mating systems, from monogamy to promiscuity. Prairie voles *Microtus ochrogaster* have been extensively studied and males can be either monogamous or polygynous. Those monogamous long-term bonders guard females from other males. Within dominance hierarchies, dominant males Cape ground squirrels *Xerus inauris* enjoy greater reproductive success as they are more outstanding in guarding females.

Precopulatory mechanisms include overtaking conflicts, such as vigorously preventing rivals to access females by guarding them. Postcopulatory mechanisms include copulatory plugs to delay female remating. Precedence for matings is also common among rodents. Mate order effects influence the male strategy. If there is a first male advantage, such as Belding's ground squirrel *Urocitellus beldingi*, males resume search as soon as copulation is completed. However, if there is a last male advantage, like Idaho ground squirrel *Spermophilus brunneus*, mate guarding is likely to be a mechanism to reduce sperm competition. Male maras *Dolichotis patagonum* typically mark estrous females by urinating on them. Some researchers agree that male urination on females could be olfactory mate guarding, but the diverse context of this behavior leaves plenty of room for other theories. In many prairie dog species (*Cynomys ludovicianus*, *C. parvidens*, and *C. gunnisoni*), the male sequesters the estrous female in a burrow with only one exit and he protects the burrow, preventing her from exiting and preventing other males from entering.

Among bats, polygynous species such as *Uroderma bilobatum*, *Vampyressa nymphaea* and *Artibeus* sp., males defend critical resources that are important to females and they defend these resources in order to gain reproductive access to those females. Therefore, this represents a form of mate guarding. In other species, such as *Myotis daubentonii*, sperm is stored and ovulation and fertilization occur seasons later, making mate guarding practically impossible.

Interestingly, the brown hare *Lepus europaeus* hybridize with the mountain hare *L. timidus* and different guarding behaviors have been observed in

interspecific sexual interactions. Dominant brown hare males mate guard females that is close to oestrus. If males from both species court a mountain hare female, the brown hare male simply chase away the mountain hare male. The mountain hare female will be limited to interact with the brown hare male as she approaches oestrus.

**Ungulata** Ungulates present a territorial harem defense, in which males are territorial and females are gregarious. The male, usually one, guards and protects the females, mating with all (or most) of them. Yet, association does not last long, remaining until parturition. The formation of harem is associated with a lot of stress for the male that, not infrequently, is depleted at the end of the mating season. Some bucks reduce up to 20–30% of its body mass during breeding season and some even die of starvation and wounds caused by fights. However, both sexes benefits from mate guarding: males defend their own reproductive interests and, consequently, they augment foraging and reproductive success of his harem.

**Cetacea** High mobile females, such as cetaceans, may limit opportunities and benefits of mate guarding. Monitoring female movement, maintaining proximity, and supervising potential rivals are energetically costly. For these reasons, mate guarding is an uncommon male tactic among cetaceans. Dall's porpoise *Phocoenoides dalli* males present close proximity with females and of lengthy nature (several hours and possibly days). These guarding males show shorter dives, suggesting that they spend less time foraging deep and more time guarding. Factors that facilitate this lasting mate guarding behavior remain unknown. Female odontocetes are spontaneous multiovulators. Theory suggests that either they stay receptive for long periods or males are unable to anticipate the timing of ovulation (or both), favoring extended mate guarding. Guarding may have substantial costs for male weight and general condition, but male Dall's porpoise increases its body mass at the onset of female oestrus, supporting that they buffer energetic deficit and curtail condition decline over the breeding period.

In bottlenose dolphins *Tursiops truncatus*, male duos and trios formed consortships with

single females up to several weeks. A consortship is an association between a dyad (in this case, the male coalition and the single female). These male pairs and triples traveled up to two body lengths away from the female, behind or flanking her. The female is coerced to stay close, with males using vocal or physical threats to keep her close.

**Carnivora** There are several social representatives in carnivorans and many societies show high reproductive skew, with a dominant pair (or alpha pair) Monopolizing up to 90% of the breeding opportunities within a group. Dominant males are thus capable of guarding the dominant female due to its high-ranking hierarchy. It is not uncommon, though, that dominant males are cuckolded, or, in other words, that his female partner seeks for other male (see “► [Extra-Pair Copulation](#)” entry). Despite the amount of time spent alone, many dominant males do not monopolize entirely the paternity of a litter, as seen in dwarf mongoose *Helogale parvula*, African wild dogs *Lycaon pictus*, and meerkats *Suricatta suricatta*. Many pinnipeds (walruses, sea lions, and true seals) have harems. One male protects and guards a large set of females by competing, sometimes aggressively, with male invaders.

**Primates** Copulatory plugs are common among mammals and even more so among primates. Moreover large testis size is correlated with high sperm competition since they are required to sustain an increased volume of sperm production in order to outcompete mates. Some groups are composed of multiple individuals of each sex (named multimale-multifemale mating systems), such as macaques (*Macaca* spp.) and chimpanzees (*Pan troglodytes*); females usually copulate with two or more males when conception is imminent. Non-gregarious primates such as nocturnal prosimians also show large testes and females are too expected to mate with more than one male. Conversely, monogamous species such as the owl monkeys *Aotus* and gibbons or polygynous species tend to have relatively small testes because females mate with a single male and sperm competition is not as likely to occur. Even with this variety of strategies, nearly all primates present

copulatory plugs, from a more rudimentary type (seminal coagulation) to a more complex type (semisolid plug that molded to the female's vagina). Although the copulatory plug serves well as "chastity belt," it may also function to help sperm survival and leakage.

Although no primate sperm seems to be completely fluid, neotropical primates still needs further research to confirm this general trend. For instance, some howler monkey species have fluid semen and small testes. Nonetheless, males are notorious for its high volume howls emitted by its utterly adapted hyoid bone and larynx. Louder males are more capable of female monopolization, and selection pressure is relaxed on testes among *Alouatta* genus, limiting the need of sperm competition. Could vocalization be a sonorous way to mate guard?

**Humans** The strong desire for privacy during sex could reflect guarding intentions by humans. Despite their serial monogamous behavior, half of men and half of women have or wish to have engaged in extra pair encounters. Moreover, women are usually referred as "concealed ovulators" due to lack of obvious signals of her fertile period. Subtle changes, such as increased symmetry and odor alterations, follow up their menstrual cycle. However, men cannot discern consciously and it usually takes a considerable amount of time spent together for men to perceive these alterations. Both issues favors long pair bonds and high paternal reliability among humans. Buss (2002) stated that there are currently about 20 different mate guarding tactics among humans, such as vigilance (calling at unexpectedly to check up on partner); violence (beat up rivals); mate concealment (be not accompanied in public by the partner); time monopolization (spending all free time with partner); verbal threat; rival denigration; physical signs of possession (hold hands); resource display (expensive gifts); appearance enhancement; sexual inducement; and possessive ornamentation (wedding rings).

### Birds

Birds have an interesting energetic feature. Flying is 15 times higher than basal metabolism, when

compared to walking that is only 1 to 2 times higher. Thus, it is less energetically costly to stay on the ground than fly to flight. Additionally, many birds are monogamous, a mating system considered as an extended mate guarding. Therefore, extra pair copulation is also commonly observed among birds and most of the studies focus on both. Male birds have then evolved a wide array of tactics to avoid cuckoldry, such as frequent mating and mate guard. Mate guarding determination of a male is directly related to the risk of extra pair copulation.

Conspicuous large birds that feed in the open are more likely to present mate guarding, such as the rheas *Rhea americana*, combe ducks *Sarkidiornis melanotos* and the red junglefowl *Gallus gallus*. Not surprisingly, female pheasants *Phasianus colchicus* remain with a single male as he relies on vigilance to escape from predators and to detect other males, a system similar to those of ungulates. Males are too large to hide in vegetation, and like many other large birds and mammals that live in the open, vigilance takes a good proportion of their actions. While, again, males spend less time feeding when accompanying their females, females gain protection. Escorted females spend three times more feeding, a system indeed similar to those observed in ungulates.

Female passerine birds are not gregarious, and males, instead of guarding individuals, guard areas or territories that contain females, with bonding persisting through incubation. Unlike polygynous mammals, polygynous male birds try to attract females instead of controlling them. Therefore, mate guarding is not as common in this group as it is in large ground-dwelling polygynous species, such as pheasants.

Procellariiforms seabirds such as the colonial *Fulmarus glacialis* are among the longest living birds and present high fidelity to both mate and nest site. Both parents care for the single laid egg and share similar portions of parental care. However, this species store sperm for several weeks after mating and the female stays without any contact with the male for a long period (up to 38 days) for the pre-laying foraging period. This susceptibility is a perfect scenario for sperm competition and extra pair copulation,

so that males need to be resourceful to counterbalance it. Males are the first to arrive and last to leave in nesting sites to keep an eye on his partner.

Among cooperative breeders such as woodpeckers, the presence of multiple males in a social unit sharply increases the likelihood of kleptogamy and selection for more intense mate guarding is strong. Groups with single males present very low frequencies of attendance and following behaviors, considered as by-products of sociality and not true mate guarding. In other words, mate guard functions as within-group mating prevention rather than between groups. If a group presents two breeding males, both will probably share their mate guarding intensity. However, if one of the two copulated first with the female, the other would apply a takeover maneuver to prevent cloacal contact, such as flying into the pair, mounting both, or pecking them. Presence of helpers also plays an important role as workload is diluted among the group individuals. Helpers free breeding males from territory defense and tree maintenance duties allowing breeding males to focus on mate guarding. Acorn woodpeckers *Melanerpes formicivorus* mate guard way earlier than expected and their social system may again explain this observed behavior as the costs of taking too long to start mate guarding are high.

White crowned sparrows *Zonotrichia leucophrys gambelii* are also monogamous and, although males do not incubate eggs, they contribute to parental care by feeding offspring. While his mate is sexually receptive, the male increase territorial defense. Conversely, bank swallows (*Riparia riparia*) guard their mates when they are sexually receptive but seek extra pair matings when the female is incubating.

Communal species (or colonially breeding species) are unable to guard efficiently their mates because at least one of the two must guard the nest site against conspecifics intruders. Extra pair copulation in these species is highly frequent and is considered as the main disadvantage of colonial breeding.

Many bird species imprint (young birds' mode of learning any specific characteristics that enables it to find conspecifics, separated between filial and sexual imprinting). Ducks are among the most familiar imprinters, but there are other representatives, such as great tits *Parus major* and blue tits *Cyanistes caeruleus*. In an interesting study between these two species, Hansen et al. (2009) cross-fostered males. Although cross-fostered great tits guarded, they guarded less than control males, both in terms of distance and degree of following, regardless of the female species. Cross-fostering clearly affected their guarding behavior as they failed to perceive conspecific partners. Imprinting behavior partially explains why many bird species end up forming same-sex pair bonds or engaging same-sex sexual behavior (male geese *Anser anser*, mallard ducks *Anas platyrhynchos*, and Japanese quails *Coturnix coturnix japonica*).

## Conclusions

Mate guarding enhances paternity of the one guarding, but the guarding individual suffers from decreased body condition. Mate guarding is consistently reported in males due to differences in reproductive strategies between the two sexes: males produce tiny and numerous sperm and females produce large and rare ova. Thus, nearly every male will compete for an egg at least once in their lifetime. Mate guarding is more pronounced when availability of females is brief, either due to short breeding seasons or due to short fertile period. Mate guarding evolved to reassure paternity of the guarding male, although evolution should also confer some selective advantage to the female. Guarded females will be more protected against predators and against other males, whose attempts may constitute energy waste and injuries to the female and/or her eggs. Conversely, the female's interest may not be aligned to her guarding male's, and his presence may interfere with her foraging success. In species in which males are larger than

females, larger males guard more efficiently. However, in species where females larger than males is the rule, larger females are generally associated with higher fecundity and, thus, those are the ones more likely to be guarded and competed for. Mate guarding may be of sonorous nature, as observed in frogs; chemical by means of copulatory plugs; mechanical by the grasp of male beetle, or behavioral, when the male fights with other males and follow up an oestrus female until she becomes receptive. Mate guard can occur many days prior to fertilization and last for a lifetime after copula (monogamy). Female mate guarding has been only observed in birds (so far). Mate guarding tactic of female birds is to request frequent copula. By this, she will lead the male to exhaustion, emptying his sperm stock and energy reserves.

## Synonyms

Mate protection; Nuptial gift; Resource provisioning; Sexual cannibalism

## Definition

Providing one's sexual partner, or a prospective sexual partner, with material resources (such as food) or protection from predators or intrasexual competitors.

In many sexually reproducing species, one sex often will provision a member of the other sex with protection, food, or other resources to gain or maintain sexual access. Females are typically the sex with a larger obligate parental investment for offspring production, and as a result, males exert greater mating effort to gain sexual access to females. Males of many species exert mating effort by provisioning females with protection or material resources, sometimes in the form of a "nuptial gift."

## Nuptial Gifts

Nuptial gifts often are provisioned as a nutritional resource. For example, males in several avian species engage in courtship feeding, wherein they feed prey to their female partner (Jawor and Breitwisch 2006; Mougeot et al. 2006), and male scorpion flies gift females with dead insects or secretions from their salivary glands (Liu and Hua 2010; Thornhill 1981). In several species of spider, including the fishing spider, males offer themselves as a nuptial gift, being devoured by the female while and after they deposit their sperm in the female's reproductive tract (Arnqvist and Henriksson 1997).

Evidence from tribal and postindustrial societies suggests that humans also provision resources to prospective mating partners, though the type of resource provisioned varies across cultures. Several articles reviewing evidence from tribal societies suggest that men may provision food, and in particular meat, to attract mating partners (Bird 1999; Hawkes and Bird 2002; Jaeggi and Gurven 2013). Evidence from a Western, industrialized population suggests a similar pattern, with participants judging displays of resource potential to be the most effective strategy for men pursuing a long-term, romantic relationship (Schmitt and Buss 1996). However, participants from the same study judged immediately giving resources to be the most effective strategy for men pursuing a short-term sexual partner, indicating that the type of relationship pursued is important when considering the effectiveness of different provisioning strategies.

## Protection

Males may also provision their current or prospective mating partners with protection, either from predators or from sexually coercive males. Protection against rival males (also referred to as mate guarding) has the dual adaptive benefit of protecting against cuckoldry for males and protecting against copulation attempts from undesirable mates for females. Research involving mate protection behaviors in several avian species provides evidence for the adaptive benefits to females of protection by a male partner (Hogstad 2015; Lemmon et al. 1997). Specifically, partnered female willow tits received less aggression and experienced a higher foraging rate relative to unpartnered female willow tits (Hogstad 2015). A study of black-capped chickadees found similar results, observing that females paired to alpha males experienced less frequent aggression and a higher feeding rate (Lemmon et al. 1997).

Mate protection behaviors have also been observed in humans; however, these protection strategies have mostly been researched in the context of mate guarding against rival men, rather than protecting one's partner from nonsexual

harms. Several studies have identified a range of strategies that men report using in their long-term romantic relationships to guard against mate poaching by rivals (Buss 1988; Buss and Shackelford 1997). There has also been research investigating the potential benefits that women may receive as a result of mate guarding. Hughes et al. (2004) found that, among college students, women are more likely to initiate sleeping with their sexual partner after intercourse. Hughes and colleagues suggested that, similar to other forms of mate guarding, sleeping with one's sexual partner may serve the adaptive function of guarding against cuckoldry for men and protecting against forced copulation from other men for women.

Males of many sexually reproducing species, including humans, exert mating effort in order to gain sexual access to females. This mating effort often takes the form of provisioning gifts or protection to the female. Mate provisioning is one method by which males compete with one another for access to mating opportunities, and therefore, a male's ability to provision protection or resources can have considerable consequences for his reproductive success.

## Synonyms

Mother's behavior

## Definition

Set of behavioral patterns exhibited by the female parent.

## Introduction

Maternal behavior encompasses all the responses and behaviors displayed by the mother towards her offspring. These behaviors ensure the survival of the offspring and its effective development and growth, both mentally and physically (Wang and Storm 2011). Mothers are often the primary caregivers in mammals. However, in many other species, fathers contribute substantially to parental care. Providing food, warmth, shelter, protection from predators, and grooming are some of these behaviors. Maternal care entails prolonged interaction with the offspring, usually spanning days, months, or even years. Variation, with respect to intensity and frequency, is observed when relating these behaviors to the temporal stage of offspring development. During gestation, aggression towards intruders and nest building behaviors are observed. At parturition, many mothers, especially mammalian mothers, consume amniotic fluids and placenta (placentophagia). These

behaviors provide nutrition to the mother, facilitate lactogenesis, and have many other benefits. After the birth of offspring, two types of behaviors are observed, those directed at the offspring and those indirectly correlated with the offspring. Active nursing, retrieval of pup, licking, and grooming are few examples of offspring-directed behaviors. Protection of offspring from threats, nest building, lactational hyperphagia, or elevated levels of food consumption are few examples of indirectly associated offspring directed behaviors (Bridges 2015). Maternal behaviors in oviparous animals include egg-laying site selection, egg-attending, burrowing, nest building, brooding, etc. In viviparous animals, provision of food, nursing, defense of offspring, and teaching of sustaining skills are some distinctive maternal behaviors (Dulac et al. 2014).

## Types

There are various types of parental care among mammalian neonates that differ with respect to the maturity of the newborn like altricial, intermediate, and precocial. Nature of care is further determined by the postnatal growth rate, litter size, social structure, etc. In the altricial type, the mother gives birth to immature young ones. They are characterized by blindness and deafness, with limited locomotor and sensory capabilities. The offspring are overly dependent on their mothers for basic processes such as urination and defecation. The mother licks the anogenital area, thereby stimulating it, and this stimulation facilitates urination and defecation in the young. In addition, the offspring lack fur and are unable to regulate their body temperatures. Nesting patterns are crucial to the altricial type of animal rearing. The mother gives birth to many offspring at the same time; hence, the one-on-one emotional bonding between the mother and each offspring is infrequent. Some examples of animals in which altricial type of maternal care is observed include mice, rabbits, rats, hamsters, squirrels, etc. (Kendrick et al. 1997; Levy 2016).

Precocial is another type of rearing in which the mothers give birth to fully developed young.

The offspring are characterized by relatively mature locomotor and sensory capabilities and are able to regulate their body temperatures and stand up, after some time, if not immediately. Nesting behaviors are almost never detected. The mother gives birth to a small litter (one or two offsprings). This helps the mother distinguish her offspring from other infants. The mother forms an attachment with her offspring and may show hostile behavior towards other infants who approach her for milk. Hence, they develop discriminative maternal care, whereby they reject other infants and favor their offspring. Some examples include sheep, goat, horse, deer, and cattle (Kendrick et al. 1997; Levy 2016).

The third type is termed as the intermediate type. Maternal care in this type can be classified as semi-altricial and semi-precocial. They are characterized by functional hearing and vision modalities but limited locomotion and thermoregulation. Some species do build nests, while some carry their young ones. The litter size is small, and the mother gives birth to one or two offspring. The mother shows maternal care only towards her own offspring but doesn't necessarily reject other infants like the ungulates. Such type of maternal care is observed in primates, humans, and suids (e.g., pigs) (Kendrick et al. 1997; Levy 2016).

## Neurobiology Behind Maternal Behavior

Maternal care often comprises detection and processing of offspring-related cues and indulging in behaviors such as licking, grooming, nest building, etc. (Kohl et al. 2017). There are two neurobiological circuits underlying maternal care, one that suppresses and the other that promotes maternal care.

Offspring-directed aggression has neurobiological correlates such as detection of cues by vomeronasal organ (VNO) and processing of these cues by medial amygdala and bed nucleus of stria terminalis (Kohl et al. 2017). Inhibition of maternal care and initial avoidance behaviors in virgin rats are linked to the medial amygdala that receives direct projections from accessory olfactory bulb.

Stimulation of main olfactory epithelium (MOE), tactile, and auditory pathways by a stimulus that is generated by offspring leads to constructive maternal behaviors. An important brain region underlying positive parental care is the median preoptic area (MPOA). Lesions in this area result in diminished motor activity on the caregiver's part, e.g., offspring retrieval. Onset and maintenance of maternal behavior are disturbed by deafferentation, chemical inactivation, and excitotoxic lesions in this area (Fang et al. 2018). Studies show that maternal behavior is aided by direct hormonal stimulation of MPOA. Pregnancy-related hormone receptors and modulators are highly exhibited in this area (Kohl et al. 2017).

The MPOA neurons are GABAergic, and therefore they exert their control via inhibition. Multisensory offspring cues are integrated at the MPOA neurons, which then send their projections directly to nucleus accumbens or indirectly via the ventral tegmental area (VTA) or retrorubral field. The dopaminergic neurons of the VTA mediate motor activities such as pup retrieval. This one-to-many organization of projections helps coordinate the complex expression of maternal behaviors. The paraventricular nucleus (PVN) of hypothalamus and dorsal raphe (DR) regulates this motivational pathway. The neuronal circuits mediating onset and maintenance of maternal behaviors are disparate, with the PVN more directly involved in maternal care induction (Kendrick et al. 1997). MPOA neurons expressing the neuropeptide galanin are essential in regulating the proper execution of parenting behaviors. Ablation of these neurons leads to impairment of crouching behavior, pup retrieval, nest building, and other critical maternal care behaviors (Kohl et al. 2017).

## Endocrinology

Multiple similarities and differences have been observed across species with respect to hormonal influences in mediating maternal behavior. It is debatable as to whether these hormones are essential for exhibiting maternal care. The peripartum period is distinguished by fluctuations in steroidal

hormones. During gestation, levels of estrogen and progesterone rise. These hormones, along with protein hormones such as oxytocin and prolactin, are known to activate maternal behavior. When progesterone levels fluctuate, uterine contractions are induced, and that is further boosted by the release of oxytocin. Prolactin levels rise in concordance with parturition thereby facilitating milk production. Oxytocin mediates milk ejection in response to offspring's suckling. Neuropeptides and steroidal hormones have both short-term and long-term effects. Short-term effects include membrane potential modulation, whereas long-term effects include gene expression modulation (Kohl et al. 2017). These hormones work closely with MPOA neurons to regulate maternal expression.

Estradiol 17 beta, the active form of estrogen, plays an important role in stimulating maternal behavior in various species such as sheep, mice, nonhuman primates, etc. These behaviors are mediated by estrogen receptor alpha (ESR1). One of the brain regions that express the highest levels of ESR1 is the MPOA, thus implying that estrogen is crucial in motivating maternal care (Bridges 2015).

Progesterone promotes gestation and regulates lactogenesis as well as maternal expression. It primes the brain to be sensitive to the offspring's cues at parturition and regulates the timing of this heightened sensitivity (Bridges 2015). Progesterone activity is mediated by progesterone receptor-mediated ligand-dependent nuclear transcriptional factors.

Intracerebroventricular (ICV) infusions of oxytocin in rat brain demonstrate short-latency maternal responses in virgin females. Delayed postpartum maternal behavior is demonstrated to be associated with lesions in this area. Oxytocin antagonist infusions into the olfactory bulb negatively affect the onset of maternal behavior (Levy 2016). MPOA and VTA are other sites of oxytocin action. Oxytocin's action is more evident in estrogen-primed or anosmic females (Kendrick et al. 1997). Maternal responsiveness is stimulated by prolactin in prior steroidal-primed virgin rats. Rapid onset of maternal care is observed in

such rats after infusions of prolactin and placental lactogens into the MPOA. Offspring retrieval and crouching behavior are known to be promoted by prolactin.

Neurotransmitters such as dopamine, norepinephrine, serotonin, galanin, etc. are implicated in maternal behavior. Dopamine is associated with both induction and maintenance of maternal care. The onset of maternal care has been linked to dopamine D1 receptor in the nucleus accumbens. Blockage of dopamine D2 receptor hampers maternal care but fails to prevent the establishment of maternal memory. Studies show that olfactory learning of offspring recognition in ewe is mediated by beta-adrenergic receptors of the olfactory bulb. Selected aspects of maternal expression are correlated to relative noradrenergic tone. Serotonin is another decisive neurotransmitter regulating maternal care. Lesions of median raphe impair offspring-associated responses and postpartum care (Bridges 2015).

## Stress

Experiencing stress while carrying out the duties of a parent is a common phenomenon. Parenting stress is a set of processes that result in detrimental physiological and psychological reactions in response to attempts at adapting to parenthood. Moderate levels of this type of stress can be correlated with effective maternal motivation. However, high levels have a myriad of detrimental effects. Negative parent-offspring relationship, harsh and reactive parenting, and impairment of the well-being of the mother are some examples of deleterious effects of maternal stress. Studies have shown that maternal love is mediated by brain regions such as the right orbitofrontal cortex, anterior insular cortex, periaqueductal gray region, and basal ganglia. Chronic and acute stress hinders functions of these regions, especially the orbitofrontal cortex causing emotion dysregulation, etc. Therefore, it is inferred that the orbitofrontal cortex is related to stress resilience (Noriuchi et al. 2019).

In addition, maternal distress is closely linked with infant developmental delay. Studies conducted on rat and monkey elucidate this relationship. If the gestating mothers are exposed to stressors such as electric shock and loud noises, many permanent alterations are observed in the offspring. Alterations in social and sexual behaviors, reduced adaptive and exploratory behaviors, delayed motor development, and impaired attention and learning are some of the effects (Mulder et al. 2002).

## Diet

Diet is commonly acknowledged to be closely correlated with behavioral outcomes. Moderate and severe vitamin B12 deficiency is known to result in negligent maternal behavior in mice. The occurrence of anxiety and depression phenotypes is observed in such micronutrient-deficient mothers (Ghosh et al. 2018). Severe maternal undernutrition during pregnancy affects glucose metabolism in the offspring. In rats, impairment of insulin sensitivity and hypertension are detected in offspring in response to restricted maternal protein intake. In the presence of limited nutrient availability in the environment, the mitochondria in the fetus greatly enhance its activity. Consequently, reactive oxygen species (ROS) levels also rise, causing oxidative stress buildup inside the cell. This leads to metabolic changes in offspring.

Conversely, increased nutrient availability during pregnancy leads to obesity in offspring. Obesity is correlated with inflammation and oxidative stress. In addition, it is known that it exerts its detrimental effects via mitochondrial dysfunction (Rando and Simmons 2015).

## Animals in Focus

### Domestic Sheep

Immediately after parturition, a bonding period is observed between the ewe and the lamb that is characterized by intensive grooming behavior

and frequent low-pitched vocalization. However, this behavior declines after a few hours of parturition. Sheep are precocial animals, i.e., the lambs are mature and are able to perform most of the essential functions on their own. There are differences among species of sheep in relation to maternal “styles” of parenting. The Suffolk ewes are predominantly rejecting, whereas the Blackface ewes are infrequently rejecting mothers. Maternal experience differentially affects few features of maternal behavior, such as a reduction in aggression towards offspring, noncooperation with sucking behavior, etc. These effects are independent of other maternal behaviors such as grooming (Dwyer and Lawrence 2000).

### Cattle

Prior to calving, the female cow separates from the herd and selects a nesting site. Cattle, like other precocial animals, invest little effort in building a nest. Standing bouts increase by 80%, and they become restless. Calving is accomplished in a recumbent position.

Licking and grooming behaviors are observed in the first hours after parturition. These behaviors help dry the calf's coat to reduce evaporative heat loss and help establish a familial bond. Lack of licking is associated with impaired maternal behavior, due to the fact that the mothers haven't learned the calf's odor. Maternal experience is a strong determinant of the occurrence of such behaviors. Ingestion of the placenta (placentophagia) postparturition is often observed (von Keyserlingk and Weary 2007).

### Wild Orangutan

Young Bornean orangutans are solely dependent on their mother's milk for nutrition. Solid foods are incorporated in diet after 12–18 months. Increased fruit availability lessens infant demand for mother's milk and allows the mother to replenish energetic reserves. Infants usually suckle and nest inconspicuously in their arboreal environment. They are characterized by late ages at weaning, female growth cessation, and reproductive maturation (Smith et al. 2017).

## Old-World Monkey

Regular allomaternal care such as playing with infants, carrying, protecting, socializing, handling, etc. is generally absent in old-world monkeys. Nonetheless, there are some exceptions such as the golden snub-nosed monkey (*Rhinopithecus roxellana*, Colobinae). Approximately 87% of infants are allonursed, and this behavior is broadly confined to the first 3 months of an infant's life. Allomaternal nursing was further characterized by kin selection and reciprocity hypotheses that state that the allonursers are related to the infants and the mothers reciprocally nurse each other's offspring (Xiang et al. 2019).

## Conclusion

All types of behavior exhibited by the mother towards her offspring(s) that ensure their survival constitute maternal behavior. Maternal care varies along a wide spectrum of behaviors that are usually unique to a specific species. Maternal behavior is regulated by an integrated neural circuitry, the median preoptic area (MPOA), which promotes active maternal behavior. This is also highly dependent on the hormone levels, such as estrogen, progesterone, oxytocin, prolactin, etc. High levels of parenting stress and inadequate diet can hamper effective maternal care expression. Maternal behavior is critical for upholding the welfare and grooming of the offspring and, hence, is crucial for the perpetuation of species.

### Introduction

Reproduction is the obligatory process to uphold the gene pool from generation to generation for any existing species. Among the other reproductive processes, mating fulfills the purpose of sexual reproduction by pairing of either two opposite sexually reproducing animals or hermaphrodite organisms in terms of copulation for insemination and subsequent internal fertilization. The term mating not only applied for higher vertebrates but also for bacteria, archaea, and viruses where formation of recombinant progeny occurs from the exchange of genomic information from the involved paired individuals. To understand mating, we must focus on its all arms, i.e., mating system, sexual selection, and sexual conflict.

## Mating System

Mating is initially dependent upon the mating system which itself is a circumstance based on which an organism shows its sexual behavior and further mate choice or sexual selection occurs. This mating system includes monogamy, polygamy (i.e., polygyny, polyandry, and gynandry), and promiscuity. Reproductive system can be asexual, sexual, or mixed type. Mating is only relevant to those organisms which undergo sexual reproduction. Thus, mating system possesses a possible span of continuum that ranges from 100% inbreeding to 100% outcrossing. Basically, the mating system follows Hardy-Weinberg law and thus gives chance to combine the allele within the individual in a population. In outcrossing organisms, new combination of genes occur, which further lead to different genotypes with high frequency of genotype diversity within populations. This outcrossing also put higher potential for rapid adaptations in changing environments. Due to homozygosity or derived from common ancestors, the inbreeding organism doesn't show diverged genotype. Mating systems confirm further the sexual selection processes in the species by affecting mate choice outcomes. In case of plants, the mating system refers to the degree and environments of the crossing, while in case of humans, mating system encompasses the formation of social relationships such as marriage. The mating system can further divide into plant, microorganisms, and animal mating system (Fig. 1).

### Plant Mating System

Plant mating system is mainly of two types, primary mating systems and mixed mating system. In primary mating system, plants can be outcrossed or cross-fertilized, autogamy or self-fertilized, and apomixis or asexual reproductive. Mixed mating system of plants follows mixed mating model which is more basic model; it reduces the complicity of other mating assumption models and assumes that any plant is either autogamy or randomly outcrossed. According to mixed mating model, plants use two or all three

**Mating, Fig. 1** Type of mating system in general

primary mating systems (Brown et al. 1989). Other than the basic mixed mating model, plant mating probability can also be assumed more efficiently by effective selfing model, developed by Kermit Ritland on the 1980s, which recognizes that closely related plants mate more effectively than that of with distantly related plants (Brown et al. 1989).

### Microorganism Mating System

Microorganisms also show three types of mating systems; asexual (by mitosis), mixed, and sexual (by meiosis). Bacteria and viruses reproduce asexually, while fungi and oomycetes can reproduce either asexual, sexual, or mixture mating.

Mating in bacteria mostly occur as homologous recombination where DNA of the donor bacteria transfer and incorporate into the genome of the recipient bacteria. This transfer of the DNA occurs either by transformation or transduction (bacteriophage mediated) or conjugation (plasmid mediated) (Chen and Dubnau 2004). Transformation basically depends on the products of the numerous bacterial genes which crosstalk with each other in a complex way to perform this process and the recipient bacteria accept the transferred DNA (Chen and Dubnau 2004). Before taking up and recombining the donor DNA into its own chromosome, the recipient bacteria enters

its natural competence. For example, *Bacillus subtilis* requires crosstalk of about 40 of its own gene products to procure natural competence, and then the bacterium introduces one third of the whole recipient genome inside its own chromosome (Saito et al. 2006). Among the different varieties of the bacterial species, at least 60 species can naturally able to procure their own competences (Bernstein et al. 2012).

Viruses (animal virus and bacterial virus or bacteriophage) also reproduce through mating and form recombinant virus progeny which ensures the mating interaction at the DNA level. Multiplicity reactivation (MR), a very known term in virology, is the mating between two viral genomes. In MR interaction occurs between two virus genomes, each containing inactivating genome damage within an infected cell. This way MR increases population of viable progeny viruses. For example, gene required for MR in T4 bacteriophage is same as the gene required for allelic recombination (Bernstein 1981). Many previous reports also state about the genes for MR in animal viruses such as herpes simplex virus (Michod et al. 2008), *Adenoviridae* virus (Yamamoto and Shimojo 1971), simian virus 40 (Yamamoto and Shimojo 1971; Hall 1982), *Reoviridae* (McClain and Spendlove 1966), *Vaccinia* virus (Abel 1962), etc.

## Animal Mating System

Animal mating system can be subdivided into following two mating relationships.

(a) **Monogamy:** Monogamy refers when one male shows exclusive mating relationship toward single female which often called as “pair bonding.” Two types of monogamy are facultative monogamy and obligate monogamy. When the species density is very low, mating occurs with a single member of opposite sexes is called facultative monogamy. In case of obligate monogamy, solitary female breeds within the habitat with small carrying capacity. They lack the ability to rear its litter alone and thus receive help from conspecifics (Kleiman 1977).

(b) **Polygamy:** The word polygamy is derived from Greek word *polygamia* meaning “state of marriage to many spouses,” i.e., practice of relationships among multiple opposite sexes (Brown et al. 1989; Pickett et al. 2001). According to the relationship type, polygamy can be divided into following subtypes:

(i) **Polygyny:** This type is the most practiced mating system in vertebrates where one male exclusively has relationships with two or more females. Based on organism, polygyny is of different types such as lek polygyny, resource defense polygyny, sororal polygyny and non-sororal polygyny. Lek polygyny is a polygamic mating system of insects and birds, forming lek of flock, where female especially peruse her mate choice and males neither scrutinize females before mating nor show any parental care to its offspring. Among the lek forming males, this mating system endorses profound skewed mating success (Akamatsu and Taguchi 2001). In resource defense polygyny, based on the best oviposition sites, females tend to choose a male based on male territory. Thus, male having best territory has several female partners (Dreisig 1995). For example, grayling butterflies (*Hipparchia semele*) show resource defense polygyny.

(ii) **Polyandry:** Polyandry is the exclusive relationship of one female with two or more males. This rare type of mating system is the composition of multi-female and multi-male and very commonly found in some insects, e.g., among honey bees (*Apis mellifera*), red flour beetles (*Tribolium castaneum*), desert spiders (*Stegodyphus lineatus*), field crickets (*Gryllus bimaculatus*), etc.; maximum pipefishes (*Syngnathidae phycodurus* and *S. phyllopteryx*); 1% of bird species, e.g., Jacana (*Parra jacana*) and dunnock (*Prunella modularis*); and also in few primates, e.g., marmosets and some marsupials (*Antechinus stuartii*, bandicoots). In case of honey bees, the queen use to mate with multiple drones (male) and store the sperms in her spermatheca and further use specific sperms on her will, throughout her reproductive life to fertilize eggs.

(iii) **Polygynandry:** This type of mating system is an association of multi-male, multi-female but with slight modifications, i.e., in this type of mating system, two or more males show their exclusive relationship with two or more females, and the number of partners is necessarily not to be the equal. In maximum cases the males are usually in less number than female partners. This type of mating system is common in alpine accentor (*Prunella collaris*) and red paper wasp (*Polistes carolina*) which is assumed to be the consequence of ecological and social stochastic (randomly determined) reproductive conflicts. The adults of the relationships show parental care to their child, and thus this mating system is more usually called as “communal breeding.”

(iv) **Promiscuity:** In this multi-male multi-female mating system, one sex of a social group mates with any other member of opposite sex, without showing any social relationship further, i.e., males of this mating system doesn't become the parenting partner (Fig. 2).

**Mating, Fig. 2** Types of animal mating system with schematic diagram

**Human Mating System**

The above described mating systems are idealized, but if one compares the mating system of human to other animals, humans possess a greater variety. Humans show all types of mating systems such as polyandrous relationships, polygynous, promiscuity, and monogamous. As human is a social animal, thus 83% of human societies are polygynous, and 0.05% are polyandrous (Low 2007). Hippies and some taboo culture peoples are often show promiscuity mating relationships where they believe in extra-pair copulations. Most interestingly in promiscuity relationship of new generation cultured people are believing in short-term relationship where they practice “sexual activity without emotional commitment or future involvement” (Turner 2009). Moreover, from the evolutionary perspective, females are more likely to practice monogamy, while males are polygamous. This is all due to the type of reproductive success they produce such as, in case of female, the acquired resources are more important for her reproductive success than that of the quality offspring she produces. Likewise, reproductive success is based on the number of offspring she can produce rather than the parental investments (Cartwright 2002). As culture always been affecting human lifestyle, starting from feeding habit to mating choices, the

ascertained “natural” human mating system is becoming increasingly difficult to maintain from zoological perspectives, and thus the level of genetic and societal promiscuity is highly varied across cultures (Marlowe 2003) (Fig. 3).

**Sexual Selection**

Among the evolutionary forces, sexual selection is the most powerful where individuals of one sex secure their mates in terms of offspring production at the costs of other folks of the same sex. In the description of sexual selection, in his book, Charles Darwin proposed “when the males and females of any animal species have the same general habit of life, but differ in structure, color or ornament such differences are called sexually dimorphic traits, which have been mainly caused by sexual selection” (Darwin 1859).

**Sexual Selection Induced Variance in Reproductive Success**

Darwin recognized two distinct patterns of sexual selection in nature, one is the micro-evolutionary pattern, and the other is the macro-evolutionary pattern. Micro-evolutionary sexual selection pattern is common within almost all species with separate sexes starting from plant to higher

**Mating, Fig. 3** Schematic diagram of the marriage pattern data of 849 societies collected from (Flinn and Low 1986)

animals, and this pattern affects males in a greater degree than females after specifying the sexes separately. In many species, males are perceptibly different from females and the common species name describes only the male sex, e.g. red-winged blackbird (*Aegialius phoeniceus phoeniceus*) are black with red chevron patterned wings where females are unobtrusive with dull brown in color (Searcy 1979; Weatherhead and Robertson 1979). Darwin also stated that, the exaggerated plumage, coloration, behavior, and morphology of males are correlated to each other but not necessarily to the male and female reproduction, i.e., sperm production or other physiological features of reproductive purpose. These males differ from the females of their own species in a rather random suite of phenotypic traits when considered across taxa. Darwin called these male-limited characters as “trivial” or insignificant because of the lack of correlation to the reproductive fitness.

The second pattern, i.e., macro-evolutionary sexual selection, is pragmatic across the male species within genera or families of almost all taxa, and thus these large differences in male phenotypes are the signature of a robust and rapid evolutionary force. In this pattern, the exaggerated males possess large phenotypic differences among the closely related male traits, and thus the sexual selection is rapid and strong.

As we understand from the micro-evolutionary theory and pragmatic studies of artificial selection and Mendel’s genetic theory that sexual selection acting on one sex is always slower and weaker than that of sexual selection on both sexes, because half of the genetic information in any generation comes from both parental sexes (half maternal and half paternal) (Falconer 1989).

We may consider an experimental condition to understand the micro-evolutionary perspective on both-sex selection and single-sex selection in which a captive or laboratory mice population is subjected to artificial sexual selection for increased body length in males of same age groups. Let’s first consider the artificial selection for both-sex, where males and females of same age group are taking part one by one for the selection process. Firstly, the body length of all the males are measured from that population, and higher body length males have been selected for further breeding, whereas other males with shorter body length prevented to be the parents. The strength of the selection of males can be calculated by using standardized selection differentials practiced by males or Sm, i.e., the difference in average body length between selected ( $Y^*$ ) and unselected ( $Y$ ) males divided by standard deviation (SD) of male body length. Thus, the equation will be as follows:

$$Sm = \frac{(Y^* - Y)}{SD}$$

Similarly, if we consider female selection, then the selection strength ( $Sf$ ) will be same as  $S_{\text{males}}$ , i.e., the difference in average body length between selected ( $X^*$ ) and unselected ( $X$ ) males divided by standard deviation ( $SD$ ) of male body length. So, the equation will be as follows:

$$Sf = \frac{(X^* - X)}{SD}$$

Now, we can calculate the total selection strength ( $S_{\text{total}}$ ) on present hypothetical population which is the average of the two selection differentials =  $\frac{(Sm+Sf)}{2}$ . If our both selections in males and females are equally strong, then the equation will be  $Sm = Sf = S$  or  $St = S$ .

Now, consider an example of artificial selection for single-sex, where selection occurs only on males, not on females. The male breed selection is followed by the same procedure as mentioned previously. However, females have been chosen randomly regarding body length. Due to the same mean body length values of the breeding and non-breeding females, the selection differential in females will be zero, i.e.,  $Sf = 0$ . Although, the actual selection differential in females is always less than zero, i.e.,  $Sf < 0$ , because the exaggerated traits preferred in males are selected against in females (Wallace 1868). In our hypothetical population, in the male gene pool, we selected for those genes that increase body length and thus  $Sm > 0$ , but in the female gene pool, we selected against these very same genes, so  $Sf < 0$ . Thus, the sex-specific selection differentials are always of conflicting sign, i.e.,  $Sf < 0 < Sm$ .

If we contemplate genetic information regarding body length in the  $F_1$  generation of the above selected male parents and unselected female parents, they will get only half of the genes affecting body length descending from male parents, whereas not from the female parents, as they were chosen randomly. Thus, the total selection differential is  $St = \frac{Sm}{2}$ , and if we elect on males as strongly as we did above then,  $= \frac{S}{2}$ . Thus, we

can conclude that single-sex selection is weaker half than that of both-sex selection or  $\text{sex selection} = \frac{\text{Both sex selection}}{2}$ .

As we mentioned earlier during the hypothetical experimentation, males taken were of same age groups because micro-evolutionary pattern suggests sexual selection as age-limited or stage-limited. Subjecting that male population again for artificial-sexual selection but this time supposing that the selection is executed on males at two diverse stages in the life cycle i.e., young or immature stage and adult or mature stage. At young or immature stage, the selection may favor small body length and act against males with larger body, and males only with the smallest body at this stage are permitted to mature, so in this early stage selection differential,  $Sm(\text{early}) < 0$ . Further, at adulthood of those permitted mice, selection as parents occurs to only those with the largest tails, and thus in this late stage selection differential,  $Sm(\text{late}) > 0$ . If we concentrate in understanding the genetic view of this selection, genes that upsurge the body length at all ages will experience conflicting selection pressures, and specifically they will be rejected at the first event of selection. Only those genes that incidentally act later in male life to increase body length will experience an articulate selection pressure and avoid the opposing juvenile selection. Thus, we can summon up that the total selection differential in males is the blend of these opposing components which further weakens and slower the overall strength of selection for these traits in the male sex.

Table: Sex-specific viability, reproduction, and total selection differential

| Selection | Viability              | Reproduction           | Total selection differential |
|-----------|------------------------|------------------------|------------------------------|
| Male      | $Sm(\text{early}) < 0$ | $Sm(\text{late}) > 0$  | $St > 0$                     |
| Female    | $Sf(\text{early}) < 0$ | $Sf(\text{early}) < 0$ | $St < 0$                     |

### Sexual Selection in the Reproductive Fitness

Sexual selection is correlated with reproductive fitness as well as sexual viability. Darwin argued that sexual selection depends on the struggle

among the males for possession of the female and is strong enough to pledge the opposing forces of male and female viability selection. Darwin provided justification while identifying the specific cause of sexual selection, and he mentioned, “if each male secures two or more females, many males cannot pair” (Darwin 1871, 1874). This relationship provided an intangible solution to the quantitative paradox due to the documentation of an evolutionary process responsible for the sexual divergence. Let us consider  $P_m$  as the fraction of males who are capable of mating and  $P_{nm}$  is the fraction of non-mating males. Thus, we can write as  $P_m = (1 - P_{nm})$ . If  $H$  is the average number of mates (females) per mating males ( $P_m$ ) then, the average fitness off mating males will be  $P_m(H)$ , and the average fitness off non-mating males will be  $P_{nm}(H)$  which will be zero, i.e.,  $P_{nm}(H) = 0$ , because non-mating males cannot have mates. Now, if the sex ratio ( $R$ ) is the average number of mates ( $N_f$ ) available for all males ( $N_m$ ), i.e.,  $R = \frac{N_f}{N_m}$ , where  $N_f = P_m(H) + P_{nm}(H)$  and  $N_m = P_m + P_{nm}$ ; so, rewriting the whole equation:

$$R = \frac{\{P_m(H) + P_{nm}(H)\}}{(P_m + P_{nm})}$$

or,  $1 - P_{nm} = \frac{R}{H}$ ; [because,  $P_m = (1 - P_{nm})$  &  $P_{nm}(H) = 0$ ]

or,  $P_{nm} = (1 - \frac{R}{H})$

If, we now consider sex ratio,  $R = 1$ , the equation will be as follows:

$$P_{nm} = (1 - \frac{1}{H})$$

From the above equation, it can be concluded that as the value of  $H$  increases, the value of  $P_{nm}$  will automatically increase, and this is the quantitative expression that captures what Darwin proposed.

Such conflicts between the fitness components of male viability and male reproduction may exist for many exaggerated male traits. It is often hypothesized that exaggerated male traits lower male viability by making males more conspicuous to predators (e.g., bird territorial calls, plumage,

and displays) or by imposing high energetic costs on males (e.g., male vocalizations in frogs and toads). In some species, these costs to males have been well documented. For example, only male frogs call, and calling has been shown by ecological physiologists to be extremely costly in energetic terms (Tuttle and Ryan 1981). Males of many anuran species expend large amounts of energy calling and, although more than 90% of mating will take place over three or four nights, the males might call every night for 2 or 3 months. Also, in one species, *Physalaemus pustulosus*, males are victims of frog-eating bats that use the sex-specific calls to locate their prey (Tuttle and Ryan 1981; Ryan 1983).

### Mechanism of Sexual Selection

As discussed earlier that according to Darwin, sexual selection is a special mode of natural selection where evolutionary selection occurs over the extreme sexual phenotypes. From his viewpoint of one sex micro-evolutionary selection pattern, females act as the scarce resources and to access to the females, males of that species compete among themselves. Thus, the winner male shows the higher mating success (more mates) than the males who lost the competition. To achieve this higher mating success, the selected male also improves their extreme phenotypes which also increase the fitness of that male solely, and thus the next generation blessed with these exaggerated phenotypes from the male parent. But, according to Wallace (1868), these exaggerated phenotypes can be unfavorable to the viability of that particular sex of species (mostly male).

For example, firstly, for achievement of higher mating success, only male competes with the other males of the same population, but the females do not get engaged in such activities. If, this kind of activities is necessary for the survival, then it must be expressed by both the sexes. Secondly, if the male-limited exaggerated, phenotypes are displayed only during the breeding season which comes once or twice in a year and after that those phenotypes disappear for the rest of the year (e.g., the appearance of antlers of some deer and other ungulates during breeding time and shed off after the mating season).

Wallace (1868) argued that why these exaggerated phenotypes display year-round, if these traits are advantageous, e.g., if the antler of male deer is useful for repelling predators, then why do the shed after mating time? Darwin conditionally stated about the function of extreme male traits in mate procurement but was not clear whether these traits were disadvantageous to both sexes or not as Wallace argued. For these reasons and following Darwin's view of sexual selection, we can anticipate three mechanisms of sexual selection to summon up the higher mating success:

- (I) **Male-male competition for mates:** From the viewpoint of Darwin, male-male competition for mates is the direct competition among the males of one species population during mating season for the achievement of high mating success, as he stated for sexual selection that it stands for the struggle for possession of the mates, not for the struggle for existence. The abovementioned struggle doesn't always lead to the death of loser, but can result in his few or no progeny. Therefore, 'sexual selection' is less rigorous than 'natural selection' (Darwin 1859).

Male-male competition is a common sexual selection mechanism for deer, elk, or horned beetles (Emlen 1996). Prior to the breeding season, males of these species use their antlers or horns in prolonged head-to-head combat in their own territory. The winning male then copulates with many females because of his higher reproductive fitness. In some other species, certain structures in male persist for reproductive combat but are not use in face-to-face combat, and these structures are less apparent than the abovementioned physical face-to-face combat structures. For example, in damselflies copulatory and seminal combat between males occur where they employ their caudal structure during the mating time (Eberhard 1996). These structures remove sperms of other males from the female reproductive tract (Waage 1979). Interestingly, some male species transfers a "mating plug" along with sperms which

have the capability to impede copulatory efforts of subsequent mating males (Gwynne 1984).

It is obvious that one successful male of fifty-fifty Mendelian sex ratio, if have several mates, then several males will have no mates at all. Thus, this type of sexual selection establishes the fundamental relationship between the variance in male fitness and the variance in female fitness.

- (II) **Female choice of mates:** As Wallace (1868) argued that the male exaggerated phenotypes are against the viability of those traits. Darwin believed that the male-male combat is insufficient to explain the evolution of these male-limited characters, and thus he proposed about another type sexual selection via female choice of mates. Darwin postulated "female choice for mates" as the process by which females select certain males as mates among other males. Darwin stated the reason as, "if man can in a short time give elegant carriage and beauty to his bantams, according to his standard of beauty, I can see no good reason to doubt that female birds, by selecting, during thousands of generations, the most melodious or beautiful males, according to their standard of beauty, might produce a marked effect" (Darwin 1859). But same possibility will arise just as raised in combat-related male sexual selection, i.e., if female choice of mates alone comes in the operation, then only the preferred male trait will be exaggerated which will be again against the evolutionary viability.

Now question may arise where female mate choice occurs as well as how and why it becomes operative. Basolo (1990) and Andersson (1994) reviewed experimentally in natural population that extreme ornamentations in males act as a strong preference signal for female mate choice. These studies also revealed that the reproductive fitness of a preferred male indicated by the extreme values of mating achieved by the preferred male throughout his lifetime rather than male-male combat. Here again

the same condition of having no mating for those “unsuccessful” males increase the variance in male mating success, which in turn increase the variance of male fitness. Burley and Foster (2006) performed an experiment on zebra finches, *Taeniopygia guttata castanotis*, to study the variation in female choice of mates by altering the physical condition of female zebra finches, i.e., by modest trimming of their flight feathers. After observing the results of sensitivity and companion experiments, they communally concluded as “female’s mate selectivity is dynamically adjusted based on her assessment of her own condition or mate-getting ability.”

- (III) **“Chase-away” sexual selection:** Above we discussed about two different types of sexual selections: (1) One was about the male displayed traits developed as the incidental by-product of viability selection, i.e., development of static female attraction toward the winning male (male-male combat for mate). (2) Second was the female-mate selection procedure where preferred male trait are been exaggerated by females when females get influenced by male secondary sexual traits. Here both the male display trait and female attraction increased concurrently from their positive coevolutionary feedback.

The “chase-away” sexual selection is another mode of intersexual selection which is not dependable on these above two types of selection and based on antagonistic coevolution between sexes (Holland et al. 1998). In “chase-away” sexual selection, males evolve some initial rudimentary display traits to enhance their own attractiveness toward females and among them the exaggeratedly attractive male influence females to mate in a suboptimal manner (e.g., too often, less than ideal time or ideal manner) (Holland et al. 1998). These variances further counter-select females to evolve their resistance to the male display traits, rather than preference for it. To overcome this increased threshold of female pre-existing sensory system, males further

advance more extreme display traits, and this way the “chase-away” sexual selection ensures cyclic antagonistic coevolution. This type of selection is common in peafowl (*Pavo cristatus*).

## Sexual Conflict

First question that arise about sexual conflict is what it is. Sexual conflict or sexual antagonism is the skirmish of reproduction associated optimal fitness strategies, i.e., mode and frequency of mating between male and female, leading to an evolutionary arms race (Parker 2006; Danchin et al. 2008). Now if we consider the type of sexual conflict, then it takes two major forms:

- (I) **Interlocus sexual conflict:** When a set of antagonistic alleles interact at one or more loci in both sexes, it is called as interlocus sexual conflict (Chapman et al. 2003). A well-documented example of this interlocus sexual conflict has been observed in *Drosophila melanogaster*, where a male *Drosophila* secretes its seminal fluid which not only induce females to lay eggs but also reduce her re-mating desires with another male along with shorten her life span by tumbling her fitness. This type of selection act as perpetual cycle which initiates with favored male reproductive traits which establishes male perseverance, resulting in reduced female fitness. This reduction in female fitness further maintains the evolutionary concept and evolves a counter-adaptation which is called as female resistance, leads to a co-evolutionary arm race.
- (II) **Intralocus sexual conflict:** Intralocus sexual selection is the tug of combat between natural selection on both sexes and sexual selection of either sex. As we see above in female mate choice, males of the population produce ornamentations to attract females for mating which is not only costly but also make males vulnerable to predators. The alleles which support the above phenotypic trait belong to antagonistic selection which

is basically a sexual dimorphism, maintains sexually antagonistic alleles within the population (Arnqvist and Rowe 2005).

### Different Types of Sexual Conflict

- **Infanticide:** Infanticide is a common sexual conflict observed where adults or parents predate their own juvenile or eggs. Sometime this phenomenon may be sex biased like either only male can be biased in eating the offspring or only female can predate their own juvenile or eggs. For example, male *Stegodyphus lineatus* sometimes eats their offspring, (Schneider and Lubin 1996) while females *Jacana jacana* predate their own juveniles (Emlen et al. 1989). This type of conflict is costly for both sexes, and thus they evolve some counter-adaptations in the exaggerated sex such as abortion of existing offspring upon the arrival of a new male (the Bruce effect) from obliging resistance of their young to loss minimization approaches.
- **Traumatic insemination:** Traumatic insemination is another type of sexual conflict to ensure paternity success where males pierce a female abdomen using their needlelike intromittent organ and directly incorporate sperms along with the accessory gland fluids into the female's blood. This is very commonly found in bed bug (*Cimex lectularius*, *Hesperocimex cochimiensis*) (Reinhardt et al. 2005), bat bugs (*Afrocinemex constrictus*) (Reinhardt et al. 2011), and spiders (*Harpactea sadistica*) (Milan 2009). If we consider example of *C. lectularius*, male *C. lectularius* climb up onto female *C. lectularius*, and by piercing her abdomen, male directly injects his sperm resulting in females with distinct melanized scar in the pierced region. The male not only pierce females but also other males and nymphs to lower the probability of other mating and thus increasing its own paternal success. As a result of this conflict, the females often suffer from blood leaking, wounds, the risk of infection, and the immune system having difficulty fighting off sperm in the blood which becomes detrimental to its own life span (Stutt 1999).
- **Toxic semen:** Sexual conflict by introducing toxic semen is mostly associated with fruit fly family member, i.e., *Drosophila melanogaster* and *D. hibisci* (Bretman et al. 2010). As we discussed earlier, this sexual conflict is an interlocus sexual conflict where male *Drosophila* pierces his intromittent organ within the inner wall of female genitalia and introduces toxic semen which is a mixture of sperm and accessory gland proteins (Acps) (Findlay et al. 2008) which is found in male seminal fluid. Male *Drosophila* may benefit from transporting toxic semen inside the females by keeping other males away from that mated female, but this changes the behavior and physiology (Ravi and Wolfner 2007) of those females, resulting in decreased life span (Chapman et al. 1995) and fitness (Wigby and Chapman 2005). Therefore, we can assume that male *D. melanogaster* matures other male adaptations to reimburse for mating plug deficiency and direct intra-genital traumatic insemination.
- **Spiky genitals:** This is another type of sexual conflict where extra-genital traumatic insemination in females occurs by males through his intromittent organ having spines which is used to pierce reproductive tract. This is common in bruchid beetle or bean weevil (*Callosobruchus maculatus*), but the insemination process and harm is the same as other discussed inseminations except that females that mate with virgin males were less likely to suffer genital damage than those who mated with sexually experienced males (Eady et al. 2007) and thus we may assume that some factors are present in male virgin seminal fluid which contributes less harm due to ejaculate size and the amount of sperm contained.
- **Love darts:** Love darts is a sharp "stiletto" like structure, created by males of hermaphroditic gastropod snails while copulation. Due to lengthy regeneration procedure, a single love dart is shot forcefully at a time at the female during courtship (Koene and Schulenburg 2005). It has been observed that love dart doesn't ensure mating success (Arnqvist

and Rowe 2005), but a successful love dart penetration ensures higher paternity assurance (Rogers and Chase 2001). Many snails suffer from open wounds, and sometimes death imposed by love darts (Baur 1998).

- **Forced copulation:** Forced copulation or sexual coercion is very common in a wide range of species which elicit aggression, harassment (Arnqvist and Rowe 2005), and grasping (Yong-Hong 2015) during both prior and at the time of copulation and make females suffer from detrimental effects including mental and physical loss due to forceful mating tactics. Moreover, we can say forced copulation as “rape” which is very common term use in case of human where females are forced to copulate against their will.
- **Sexual cannibalism:** In terms of sexual conflict, sexual cannibalism is an exception of traditional male-female courtship behavior where female homicides and devours males during copulation (Arnqvist and Rowe 2005). A very common example of sexual cannibalism is sexual interaction between male and female funnel-web spider, *Hololena curta* (Yong-Hong 2015). After sperm exchange, female kills and consumes the male to increase “parental investment,” i.e., female spiders consume male which serves as a blood meal since they volunteer their soma and thus increase in quality of offspring. Some male gift-giving spiders provide edible gifts to the females before sexual intercourse just to manipulate females to not kill them.
- **Anti-aphrodisiac:** Anti-aphrodisiac is a volatile compound produced only by the males of several *Heliconius* butterflies, i.e., *H. melpomene* and *H. erato*, and serves as a beneficial for both sexes. Male *Heliconius* butterfly transferrers this anti-aphrodisiac inside the females so that she smells like that male resulting in prevention of future copulation with other males as well as benefits from post-mating harassments to from males to decrease reproductive success by disturbing the production of eggs. Thus, anti-aphrodisiac increases the paternity success of the male by preventing introduction of sperms of other males resulting

in fertilization of the egg by his own sperm (Schulz et al. 2008).

## Conclusion

In this chapter we have emphasized on the basic concepts of various parameters on which a successful mating depends. The cost and benefits of mating rely on different mating systems, mating behaviors, mate selections, and sexual conflicts which are likely to vary widely within and between species. Charles Darwin clinched that the effect of cross robustness or complementation “is amply sufficient to account for the . . . genesis of the two sexes.” Meanwhile the advent of the modern evolutionary fusion in the twentieth century, numerous biologists have suggested rival explanations for this vast array of different living species maintain sexual reproduction. This diverse cost and benefits of mating possess an important consequence both on population dynamics and on the genetic structure of populations (Clutton-Brock 1985). But one may be curious about the advantages and disadvantages of mating. The main disadvantage of mating or sexual reproduction is the population expansion cost, i.e., sexual reproduction takes more investments such as energy and time, while asexual population grows in multiplication form each generation. Not only that sometimes for mate selection or mate attraction, some members of the population become vulnerable to predators, and chances become higher toward population decrease. Both in this case the natural selection theory maintains, i.e., the higher the fitness, the higher the genetic quality. Now if we consider the advantages of mating or sexual selection,

- (i) Mating can syndicate the effect of valuable mutations in the individual. Thus, mating aids to the spread of advantageous traits in the population.
- (ii) Deleterious mutations come together by mating and generate severely unfit individuals which are then eradicated from the population. Thus, mating promotes removal of deleterious genes.

- (iii) Mating also creates new gene combinations which ensures more fitness than existing ones or may simply lead to condensed competition among relatives.
- (iv) Mating is an abrasive filter, tidying out chromosomal rearrangements like major genetic changes but also authorizing minor variation, i.e., changes at the nucleotide or gene level to pass through the sexual sieve. Thus, mating promotes genetic variations via protecting population from major genetic mutations.
- (v) Mating ensures combinations of advantageous genes from two individuals. Thus, mating is a novel genotype creator.
- (vi) Mating also ensures the increasing resistance to parasites by coevolution which is also known as the Red Queen hypothesis.

## Mating Effort

Gavin Vance<sup>1</sup> and Todd K. Shackelford<sup>2</sup>

<sup>1</sup>Oakland University, Rochester, MI, USA

<sup>2</sup>Department of Psychology, Oakland University, Rochester, MI, USA

## Synonyms

Intra-sexual Competition; Parental Investment Theory

## Definition

Mating effort encompasses all the investment of resources in order to gain sexual access to a conspecific, the time and energy expended during copulation, and all the sex cells expended as a result of copulation.

Mating effort refers to the time and energy an organism invests to gain sexual access to another organism, the energy expended during sex, and the gametes (sex cells) invested. In sexually reproducing species, the sex that invests more resources in its offspring is more selective when choosing a mating partner (Trivers 1972). As a result, the sex that invests fewer parental resources will experience greater intrasexual competition for mating partners and will exert greater mating effort to reproduce sexually. The sex with lower obligate parental investment needed to produce offspring may achieve greater reproductive success by copulating with a greater number of partners. There is a range of evolved strategies expressed in mating effort, with some individuals being more competitive in terms of gaining sexual access and others having adaptations resulting in a more competitive contribution of sex cells (sperm).

## Intrasexual Competition

One way in which organisms can exert mating effort is by directly competing with same-sex

conspecifics to gain sexual access to opposite-sex conspecifics. In some species, such as peafowl, males (peacocks) display prominent physical characteristics to advertise their genetic quality (Petrie et al. 1991; Petrie and Halliday 1994). In this case, females (peahens) select as mating partners males with the most vibrant plumage. In other species, males may possess ornamentation, or “weaponry,” such as the antlers used in intrasexual competition by deer (Andersson 1994). Physical characteristics like weaponry and colorful displays of plumage constitute one type of mating effort, wherein organisms directly compete to gain sexual access.

Evidence for sex differences in mating effort has been observed in humans. Relative to women, men report a higher ideal number of lifetime sexual partners, indicate that they need less time to know someone before having sex with them (Buss and Schmitt 1993), and express greater desire for casual sex (Schmitt et al. 2001). Similar to males in many nonhuman species, men also exert mating effort to gain sexual access; however, the ways that men advertise their desirability as a mating partner often corresponds to their ability to provision the female and/or her offspring with resources. For example, both men and women in one study judged “showing resource potential” to be most effective for men pursuing a long-term partner and judged immediately gifting resources to be the most effective strategy for men pursuing a short-term sexual partner (Schmitt and Buss 1996). Whereas males of other species may exert mating effort using direct competition, including physical displays of genetic quality such as the peacock’s train, men may exert mating effort by displaying their ability to provision resources to a woman and her children. In this sense, human mating effort may be unique because, in most other species, mating effort is often framed as an alternative to parental effort. To further complicate this distinction, there is debate about whether altruism may be better understood as mating effort or as a way in which men display their ability to provision resources. Whereas some have argued that men use altruistic behavior as a means to display their genetic quality (e.g., Gintis et al. 2001), others have argued that men use altruistic

behavior to indicate their ability to provide parental care (e.g., Kokko 1998). Still others have argued that the framing of parental and mating effort as a trade-off may be misleading (Stiver and Alonzo 2009), as certain behavioral characteristics may simultaneously serve both functions.

## Sperm Competition

Males can also exert mating effort without engaging in direct competition with one another for sexual access. Adaptations for sperm competition facilitate males of some species to compete to fertilize a female's ova. Some sperm competition adaptations result in the production of higher-quality ejaculates. Chimpanzees have a larger testes-to-body weight ratio compared to many other primates, and because larger testes are capable of producing larger ejaculates, this implies an evolutionary history of frequent sperm competition (Møller 1988). Alternatively, some adaptations to sperm competition involve the removal of rival sperm. For example, one study of *Drosophila melanogaster* observed that sterile males could displace semen from the reproductive tract of females who had previously mated (Harshman and Prout 1994). In humans, the male penis has evolved a shape that is effective at removing semen from a woman's reproductive tract (Gallup et al. 2003). Research investigating sexual behavior in humans has also revealed a number of behaviors that may reflect adaptations to sperm competition. For example, men who have spent more time away from their partner since the couple's most recent copulation report greater interest in sex with her, even after controlling for time since the last copulation (Shackelford et al. 2007), potentially to displace or to compete with the sperm of rival males in the woman's reproductive tract.

Mating effort encompasses a range of physical, behavioral, and cognitive adaptations that individuals use to increase their reproductive success. In particular, males of many sexually reproducing species often face greater intrasexual competition for access to mating partners and, thus, have adaptations for intrasexual competition.

## Matrilines and Patriline

Lauren J. Wooddell

Neuroscience and Behavior, California National Primate Research Center, University of California, Davis, Davis, CA, USA

### Definition

**Matriline** a line of descent in which the intervening generations are mothers

**Patriline** a line of descent in which the intervening generations are fathers

### Social Organization via the Matriline

The organization of animal and human societies depends on kinship ties that persist either through the female line, deemed “matrilines,” or the male line, deemed “patriline.” In many animal societies, the most common form of kinship social structure is via the matriline. Matrilineal social systems commonly occur in multimale/multifemale groups in which females are promiscuous, mating with several males. Males disperse from their birth (natal) group to reduce inbreeding (mating with relatives) and due to local mate competition in which males compete for access to the females. Given the high degree of female promiscuity, the certainty of paternity is low, whereas maternity is readily identifiable. This leads to an organization where individuals tend to interact primarily with their maternal relatives, or their matriline, rather than their paternal relatives, or patriline. Matrilineal social organizations are predominant in baboons (e.g., *Papio anubis*), macaques (e.g., *Macaca mulatta*), hyenas (e.g., *Crocuta crocuta*), lions (e.g., *Panthera leo*), and many other animal species.

The support for matrilineal kin recognition is abundant, with individuals preferentially affiliating with kin via grooming interactions, proximity, and other affiliative behaviors. Individuals have also been shown to respond to vocalizations of matrilineal kin during playback experiments. During playback experiments, individuals respond, generally via enhanced looking time, to the

vocalizations of matrilineal kin. This recognition eventuates via familiarity (i.e., familiarity through associations) and phenotypic matching, the process by which individuals match similar visual and/or acoustic components to their own. Matrilineal kinship also manifests itself in the structure of the dominance hierarchy. Maternal rank inheritance is the process by which individuals attain adjacent ranks to their mothers via the cumulative support of mothers and matrilineal kin in aggressive interventions. Matrilines can therefore be ranked among one another, and individuals are also ranked within the matrilines, all of which is highly predictable via kinship relationships and highly stable over time. Occasionally however, lower ranking matrilines will jointly challenge higher ranking matrilines, resulting in a matrilineal overthrow. These violent events are rare and result in the dramatic social reorganization of a large number of individuals. Given the consequences for the social group, it is not surprising that individuals respond more strongly to the vocalizations corresponding to a matrilineal overthrow (Bergman et al. 2003), suggesting that individuals classify entire matrilines as entities, recognizing not only individual ranks, but matrilineal ranks.

The highly complex social structure of matrilines, which can have as many as four generations, can depend on matriarchs, or old females. In a number of species, matriarchs can be instrumental in survival through ecological knowledge, group leadership, stability, and grandmothering. Indeed, the loss of a matriarch can lead to group fissions along the matriline, fighting, family disputes over money, and reduced vitality of offspring and grand-offspring in a number of species. Accordingly, the “grandmother hypothesis” (O’Connell et al. 1999) poses that the long postreproductive life in humans (and some animals, e.g., orcas, *Orcinus orca*) has evolved to enhance reproductive success by caring for and helping raise grandchildren, with maternal grandmothers having the most significant influence. Indeed, matrilineal lineages can be lost at considerable rates in wild populations (Gompper et al. 1997), and the loss of grandmothers, or matriarchs, can therefore have considerable impacts on the survival of the matriline.

## Social Organization via the Patriline

Contrary to matriline, patriline generally occur in multimale/multifemale groups in which males reside in their birth group and females disperse, such as in chimpanzees (*Pan troglodytes*), African wild dogs (*Lycaon pictus*), and some birds. Females disperse either due to local resource competition in which males compete for access to a territory to attract females or when the average tenure of the male exceeds the age of females at first conception (to prevent daughters from mating with their fathers). Whereas matrilineal social organizations are predominant in animal societies, patrilineal organization is predominant in many human cultures. Cattle may have led to the transformation from matrilineal to patrilineal societies in some human cultures (Holden and Mace 2003), as the inclusion of livestock as an indicator of bride wealth may have provided more benefits for sons than daughters. Accordingly, whether males or females have greater reproductive success generally explains whether matriline or patriline occurs in human cultures. The evidence of patriline influencing the structure in many human societies is relatively ubiquitous with family name, property inheritance, and political or royal titles generally transmitted via fathers. Ancestry too is predominantly measured by genealogical markers such as the Y chromosome to detect ancestry through the paternal line (Calafell and Larmuseau 2017), although mitochondrial DNA (mtDNA) is also used to detect maternal ancestry.

While some animal species have patrilineal-like social structures, such as chimpanzees, African wild dogs, gorillas (e.g., *Gorilla gorilla*), red colobus monkeys (e.g., *Colobus badius tephrosceles*), and sac-winged bats (e.g., *Saccopteryx bilineata*), it is suggested that the only truly patrilineal social structure is in humans. Patriline requires some level of paternal kin recognition, which may require monogamy (see Chapais 2016 for a comprehensive overview) to ensure paternal certainty. While some behaviors consistent with a patrilineal society exist in animals, others appear to be absent, such as paternal rank inheritance and paternal kin recognition past primary paternal kin (see Chapais 2016). Non-human primates laid the basic foundation for

patriline, with monogamy contributing to the patrilineal kinship structures seen in humans currently.

Research is however increasingly supporting the hypothesis that animals may discriminate vocalizations of unfamiliar paternal kin, even without social experience, indicating that phenotypic matching may play a role in acoustic kin recognition. However, age proximity in individuals with social experience with one another is also likely an important social cue of paternity as well, with individuals less likely to mate with individuals of a similar age as they may have been sired from the same father. However, inbreeding is still relatively more common in patriline compared to matriline given the uncertainty of paternal relationships. Paternal lineages can also influence infant development, genetic diversity, productivity, and fitness in a number of species.

Contrary to grandmothers or matriarchs, grandfathers or patriarchs may derive little benefits of long life in monogamous human societies (Lahdenperä et al. 2007), with the patriline deriving little added reproductive success, contrary to the effect grandmothers have on their matriline, although old men may benefit the patriline in other ways (Strassmann and Kurapati 2016). The long lifespan of females has also been hypothesized to be a byproduct of male longevity (“the patriarch hypothesis,” Marlowe 2000). In this case, the benefits of grandmothers to their grandchildren are hypothesized to be indirectly related to grandfathers, or aged men. A patriline may generally be less vulnerable than a matriline, but group fissions along the patriline have been reported in some nonhuman primates and humans.

## Conclusion

Whether social groups develop matrilineal or patrilineal social organizations depends on a number of factors including sociosexual behavior, reproductive success of males and females, and paternal certainty. The kinship structure of social groups then gives rise to an interesting social structure, which can influence the development of behavior and cognition across the lifespan.

[Means-end behavior](#); [Means-end understanding](#)

## Definition

Broadly speaking means-end reasoning is concerned with finding means for achieving

goals (Pollock 2002). More specifically, it involves the deliberate and planned execution of a chain of actions to achieve a goal and occurs in situations where an obstacle (e.g., a distance between the subject and a desirable item, person) preventing the achievement of the goal must initially be removed (Willatts 1999).

## Introduction

In everyday life, we are regularly facing situations which require elaborate sequences of mediating actions to reach a distant goal at the end. For example, imagine a person opening a drawer to take a key to unlock a storeroom to get a ladder needed to reach the door to an out-of-reach vitrine where there is a candy box that can be opened to get some sweets. As this hypothetical problem-solving sequence illustrates (modified from Santos et al 2005), the individual steps within a sequence are often separated from the final goal both in time and space. To complete the sequence, problem solvers must initially ignore the primary goal (e.g., reaching the sweets) to focus on first completing the individual subgoals (e.g., getting the stepladder). Moreover, means-end behavior often requires an extensive knowledge of the causal relations between objects. In other words, an individual needs to understand both the connection between the individual steps of a chain of action (a key can open a locked door, a ladder can be used to access things that are out-of-reach, etc.) and how they relate (finding the key to the storeroom is necessary for eventually eating the sweets).

When performing a goal-directed behavior, understanding these consecutive sequences of mediating actions as the means to an end can be of significant advantage for any individual (Schmidt and Cook 2006). In fact, without such an understanding, it will be impossible for an individual to transfer an intention into an action, and arguably impossible to form an intention at all (Osthaus et al. 2005). The understanding of functional relations between an action and its consequence is thus a crucial step in cognitive development.

## Means-End Reasoning in Human and Nonhuman Animals

In human cognitive development, understanding of means-end relations develops in early infancy (Piaget and Cook 1952). Piaget was among the first to develop a task assessing this specific kind of problem-solving. In the so-called “support task,” the infant must try to obtain an object, (e.g., a toy, that is out of direct reach) by pulling a piece of cloth placed underneath the toy towards itself. In this task, the piece of cloth serves as a support and correctly using the support is the means to accomplish the end of obtaining the toy. Piaget found that the infants first acquire the ability to pull supports, but they persist in doing so even when the goal does not rest on the support (on/off condition). At a later stage (after 12 months), the infants gain conceptual knowledge about the relationship between the means and the end, the spatial relationship between the two, and the features of the support used. Furthermore, they develop cognitive processing that allows subjects to have a definite goal, to persist in trying to achieve it, and thus to produce a goal-directed behavior. Even though later work massively improved and refined the model of infant cognitive development, Piaget’s original model remains valid (Willatts 1999).

The question if and how animals develop means-end understanding remains one of the central questions of the modern comparative cognition research (e.g., Schmidt and Cook 2006). Analyzing the understanding of means-ends relationships in nonhuman animals requires problem-solving tasks in which a solution to the problem can in principle be perceived directly, without trial and error or previous experience of similar tasks. Means-end understanding is thought to be most clearly demonstrated if the subject shows an “insightful” solution to the problem on the first trial, ruling out possible operant conditioning. Usually, relying on means-end connections is assessed by offering a choice of two options, one of which is in physical connection to an out-of-reach object of desire. Widely used paradigms in this context include the “string-pulling task,” originally applied by Köhler (1927), as well as the “support problem,” originally introduced by

Piaget (Piaget and Cook 1952). Both tasks involve offering a possible physical connection to an out-of-reach object of desire. In the string-pulling task, a string is attached to a piece of food. The food itself is out of reach of the animal, but the near end of the string is accessible. In the “support problem”, an object is out of the subject’s reach but is placed on a cloth which the subject can pull towards it. Both tasks – the string pulling as well as the support problem – are based on the assumption that if the animal understands the physical properties of the string or the cloth, it uses it as a means to an end, i.e., pulls the food into reach with the string or cloth on its first exposure to the task. In contrast, subjects who do not understand that pulling the string is the “means” for achieving the desired “ends” of bringing the reward within reach, will only be able to succeed via repeated exposure and associative learning (Range et al. 2012).

When offering a choice of two options, one of which is in physical connection to an out-of-reach object, the physical situations of these choice discriminations then can be varied in many ways. In each case, the food is out of reach, so the subjects need to recognize which of the physical arrangements would yield a reward. By analyzing the subjects’ performance in such simultaneous discriminations, it can be assessed whether an animal is relying on perceptual features rather than attending to the relevant functional features of the task. In the support task, subjects can choose between pulling a cloth with a piece of food on it versus pulling another piece of cloth with the same reward closely next to it (“on/off problem”). In the “connected problem”, subjects can choose between a piece of food resting on an intact piece of cloth versus a second reward resting on a cloth that is divided into two pieces and hence separated by a small gap. The nature of string-pulling task allows for a higher number of conditions since the strings can be arranged in a number of different patterns (e.g., slanted, parallel, convergent, crossed, pseudo-crossed, double-crossed and so on), commonly referred to as “patterned-string problems.”

So far, animals as diverse as monkeys, great apes, dogs, cats, elephants, pigeons, corvids, parrots, and bumblebees have been tested with the string-pulling task and/or the support problem.

Spontaneous apparently “insightful” solutions were found in just a few species, for example, in a number of nonhuman primates (Hauser et al. 1999; Herrmann et al. 2008), large-brained birds such as corvids and psittacids (e.g., Auersperg et al. 2009; Heinrich and Bugnyar 2005; Krasheninnikova et al. 2013), and elephants (Irie-Sugimoto et al. 2008). Various cognitive mechanisms underlying the pulling of strings and/or supports have been proposed for other animals, for example, associative learning (e.g., pigeons, *Columba livia*, Schmidt and Cook 2006, and bumblebee, *Bombus terrestris*, Alem et al. 2016), relying on perceptual feedback (New Caledonian crows, *Corvus moneduloides*, Taylor et al. 2010), or attending to perceptual contact but not necessarily connectivity (great apes, Povinelli 2000). Dogs as well as domestic cats (*Felis catus*), although able to learn to obtain food that is out of reach by means of an attached string, have failed to show understanding of means-end relationships when tested in a two-choice paradigm involving various patterned-string tasks (Osthaus et al. 2005; Whitt et al. 2009).

Other tasks requiring an understanding of means-end relationships involve tool use, but they also require other cognitive capacities as well, so that they are sometimes considered to be less appropriate as tests of means-end understanding as such (Osthaus et al. 2005). Nevertheless, an obvious parallel to the hypothetical problem-solving sequence, as described at the beginning of the chapter, is the sequential tool use, where a tool is used to acquire another tool (Santos et al. 2005). There are three difficulties arising from sequential tool using: (1) the subject must recognize that one object can be used as a tool that can be used on another nonfood item, (2) the subject also must forego the immediate motivation to use the first tool to attempt to access the food directly, and (3) the subject must be capable of hierarchically organized behavior (Wimpenny et al. 2009). Such sequenced behavior is exceptionally rare in the nonhuman animals. The only evidence of using tool sequences comes from nonhuman primate and large-brained birds (corvids and parrots). For example, wild chimpanzees have occasionally been observed using an additional

stone to adjust poorly positioned stone anvils; the additional stone thus provides a leveler for the anvil (Matsuzawa 2001). These observations suggest that chimpanzees can use a means, in this case the additional stone, to act on another means, the stone anvil, even in the absence of an immediate food reward. The New Caledonian crow, *Corvus moneduloides*, a habitual tool-manufacturer and tool-user in the wild, has shown sequential tool use by using a short tool to extract a longer tool that could then be used to obtain a reward (Wimpenny et al. 2009). However, it has been shown that sequential tool use is not restricted to habitual tool users only. The rooks, *Corvus frugilegus*, a non-tool-using corvid, could use a large stone to access a small stone that could be used to release an out-of-reach food (Bird and Emery 2009). In parrots, the other large-brained avian group, sequential problem-solving has been documented in the Goffin's cockatoo (*Cacatua goffiniana*). The birds could solve a five-step sequence of multiple locking devices blocking one another demonstrating that they can execute a chain of intermediate actions unaffected by the fact that the goal was very distant (Auersperg et al. 2013).

## Do Nonhuman Animals Really Perform Means-End Reasoning?

However, despite the recent impressive findings involving apparent understanding of means-end relations found in various animals, the pivotal question remains: to what degree do states of cognition characterized by terms like “means-end reasoning”, “insight”, “understanding”, and “problem solving” contribute to an animal's behaviors as opposed to “simpler” mechanisms based on experience and associative learning (Hanus 2016; Shettleworth 2012).

Obviously, mere acquisition of the reward by pulling at the string or the cloth does not necessarily reflect means-end understanding. For example, successful performance in string-pulling tasks might be based on perceptual feedback, i.e., forming an association between pulling the string and the reward coming closer, resulting in

repeated pulling (Taylor et al. 2010). Another common strategy subjects may employ when faced with patterned-string tasks or support problems is the proximity rule, i.e., pulling the string or cloth closest to the reward. Thus, it has been claimed that an animal can reasonably be said to possess means-end understanding only when pulling the support (string or cloth) is goal-directed and not dependent on such perceptual features (Jacobs and Osvath 2015).

For example, in the support task study on tamarins, the authors conclude that the subjects solved these tasks by understanding the general means-end relations mediated by the functionally relevant properties of their physical arrangement (Hauser et al. 1999). Later, this claim has been questioned by Povinelli (2000), proposing instead that primates only learn about the perceptually salient features of the task rather than about any more profound understanding of mean-ends relations. In other words, the animals were learning only how to obtain the food, based on the visually observable features of the task such as the continuous nature of the cloth or gap placement. As such, the observed transfer across different task conditions in Hauser's et al. (1999) study has been suggested to reflect the direct generalization of what was learned about these perceptual features rather than any reasoning about means-end relations. Accompanying experiments testing chimpanzees in various support and connection problems supported Povinelli's (2000) perceptual interpretation.

There are other related situations in which an animal's behavior may also suggest a failure to represent means-end relations adequately or to understand how a particular sequence of means contributes to an end (Woodward 2011). For example, animal's behavioral recipe may contain elements not necessary or superfluous for the achievement of the goal. An adequate means-end understanding would allow the animal to recognize when these superfluous elements are present and can be omitted. First evidence for such a recognition capacity comes from Goffin's cockatoos successfully responding to the functionality of each step in the chain in the five-step sequence problem-solving task. When one or more locks

were missing, the birds directed their attention to the first relevant one, ruling out a rigid learned routine (Auersperg et al. 2013). Alternatively, an animal that behaves as if it recognizes that employing a means in specific situation is sufficient for achieving the desired goal, (like a crow obtaining a short tool to use it on a longer stick to obtain the desired food reward) may, in fact, may, in fact, just employ a specific behavioral recipe or routine sufficient for reaching the goal in this specific situation. However, the animal may fail to recognize that there may be alternative means besides the employed one for the achievement of the goal, or, when a changed situation has the consequence that the original means is no longer appropriate. Furthermore, some claim that most animals, maybe even all except humans, can only deal with causal information which features their own actions as causes and outcomes as effects. In other words, an animal that only has a representation of the form “If I do action A, desired outcome O results” with no general representation of intermediate steps leading from A to O (Woodward 2011).

Probably the most challenging part of animal cognition is to rule out all the alternative explanations for “intelligent” behavior, and whether or not one or the other researcher adequately do so may remain open to debate. Nevertheless, recent findings in the context of means-end reasoning in animals provide promising and tractable empirical paradigms for investigating this challenging topic of animal cognition.

## Conclusions

Human behavior regularly involves elaborated sequences of means-end actions, but such sequences are quite rare in the natural behavior of nonhuman animals. Given recent reports about the performance of various nonhuman animals in different means-end tasks, it seems that at least some species may potentially possess a basic concept of means-end reasoning that is not directly reliant on perceptual features. However, given the likely perceptual origins of learning about means-end relations, researchers, in general, should be cautious in interpreting how animals

solve such problems, especially when the visual characteristics of the task are salient.

## Mechanoreceptors

Carmen M. Cromer and Lisa M. Paciulli  
North Carolina State University, Raleigh, NC,  
USA

## Introduction

Mechanoreception has roots in the Greek word “mechano,” meaning “machine,” and the Latin “receptiō,” meaning “to receive.” Mechanoreceptors are sensory organs that carry impulses from touch, pressure, and sound waves along nerves to the central nervous system (CNS), including the

brain. When a given mechanoreceptor is activated by external stimuli, such as touch, pressure, and/or sound waves, positive ions (electrically charged atom(s)) flow into the relevant cell. Net depolarization, or a positive change in charge, generates action potentials (APs) or electrical impulses. As the impulse travels along the nerve cell membrane, the AP synapses (connects) with nuclei (eukaryotic organelles containing genetic material) in the dorsal column of the spinal cord. Nerve fibers from this region travel upward, eventually forming synapses with nuclei in the thalamus of the brain, which relays sensory information to the cerebral mantle and somatosensory cortices. The somatosensory cortex interprets tactile (touch) information. In contrast, auditory (sound) information travels to, and is interpreted by, the primary auditory cortex. Thus, mechanoreceptors transduce mechanical energy from external stimuli (outside of the body) to biologically useful neural information for the body to use to respond to stimuli (French and Torkkeli 2009).

There are three types of mechanoreceptors. The first are mechanoreceptors that respond to tactile sensation (e.g., hair cells). The second are proprioceptors that respond to positional changes and movement of the body (e.g., muscle spindles and Golgi organs), and the third are baroreceptors that respond to changes in pressure (e.g., volume receptors). There are more tactile mechanoreceptors than proprioceptors or baroreceptors, perhaps in part because the skin constitutes the largest sensory organ in the body and provides a physical barrier and conduit between an organism's external and internal milieu. Indeed, in mammalian vertebrates, there are at least four known types of tactile mechanoreceptors, including but not limited to bulbous corpuscles, lamellar corpuscles, tactile corpuscles, and Merkel's discs.

Proprioceptors play a role in an individual's sense of balance and work with the vestibular system. In mammals, birds, reptiles, and most fish species, vibrational pressures are detected by hair cells in the cochlea of the ear. Hair cells are specialized receptors equipped with stereocilia, or small fingerlike projections. Vibrational forces induce movement of the stereocilia, which causes mechanically gated ion channels within the

sensory epithelium to open, allowing ions to enter the cell. Cations (positively charged ions such as  $\text{Na}^+$ ) enter the cell and change the cell's voltage, making it more positive. This change in voltage creates APs that are sent to the CNS and ultimately form the basis of spatial orientation. Like the vestibular system, the auditory system is also modulated by hair cells. The mechanisms of these two senses differ though primarily in the arrangement of hair cells. In proprioceptors, stereocilia in vestibular hair cells form an apex cilium (kinocilium), while auditory hair cells lack kinocilia and are arranged in a staircase-shaped formation.

## Evolution of Mechanoreceptors

The location and distribution of mechanoreceptors differ across taxa, but most types of mechanoreceptors share the same basic physiological principle: the presence of a specialized neuron that depolarizes in response to external stimuli. This indicates that throughout vertebrate evolution, mechanoreceptors have been evolutionarily conserved (Coffin et al. 2004). For example, both lampreys (agnathans or jawless fish) and gnathostomes (jawed vertebrates) have hair cells. Sensory hair cells are also found in invertebrates, but their similarity may merely reflect convergent evolution (Coffin et al. 2004). Also, ion channels sensitive to mechanical stimuli exist in bacteria, suggesting the ancient nature and function of mechanoreceptors (Manley and Ladher 2010). However, no basal ancestor of mechanoreceptors has been identified nor is the evolution of mechanoreceptors comprehensive or well understood.

## Vertebrates

Mammalian mechanoreceptors are located along the body, with clusters in locations particularly sensitive to mechanical stimuli, such as the fingertips. Tactile mechanoreceptors are located within or beneath the epidermis, the topmost layer of the skin, while Meissner's corpuscles lie just below the dermis in smooth skin, such as in

elephant trunks (Verendeev et al. 2015; Hoffmann et al. 2004). In contrast, Pacinian corpuscles are found in deeper layers of the skin in subcutaneous tissue. Meissner's corpuscles have a smaller receptive field than Pacinian corpuscles and are active when a stimulus first occurs and when the stimulus ends. Also, their response threshold is lower than that of Meissner's corpuscles, which means that Pacinian corpuscles respond faster to stimuli (Purves et al. 2001). Pacinian corpuscles are activated when they detect high-frequency vibrations (Purves et al. 2001). Both Merkel's discs (unencapsulated nerve endings) and Ruffini's corpuscles (encapsulated nerve endings) respond slowly and remain activated longer while a stimulus is occurring (Purves et al. 2001).

Bird beaks, or bills, interact with the external environment and are capable of detecting changes in pressure and velocity. Bird bills have internal mechanoreceptors with clusters of afferent neurons at the tips in some species (Cunningham et al. 2013). Afferent neurons carry nerve impulses from sensory stimuli to the central nervous system and brain. There are two types of mechanoreceptors in bird beaks, Herbst corpuscles and Grandry corpuscles, both of which detect external mechanical stimuli (Cunningham et al. 2013). The locations of the receptors within the bill depend upon multiple factors, including the species' diet, as a function of bird mechanoreceptors includes prey detection (Cunningham et al. 2013). The mechanoreceptors in primate fingertips function similarly to those in bird beaks, though they are not considered the same type of receptor, as they are morphologically different (Cunningham et al. 2013; Verendeev et al. 2015).

## Aquatic Vertebrates

Fish and other vertebrates adapted to aquatic life, such as amphibians, have evolved the lateral line system (LLS) to detect vibrations in water. The LLS allows aquatic organisms to identify objects in the surrounding environment and to respond to stimuli such as pressure gradients, vibrations, and movement of potential predators/prey. Named for a series of characteristic epithelial pores running

from the gills to the tail of the animal, the LLS consists of neuromasts or specialized hair cells located beneath the skin. Neuromasts are roughly analogous to the hair cells found in the mammalian auditory system. Some cartilaginous fish, notably sharks, have evolved electroreception and employ specialized organs, known as ampullae of Lorenzini, to detect electric potentials in water (Freitas et al. 2006; Winther-Janson et al. 2012).

## Invertebrates

Invertebrates, mostly arthropods (insects, spiders, crustaceans), also use mechanoreceptors to sense changes in their environment. One of the best-studied examples of invertebrate mechanosensation is that of the roundworm, *Caenorhabditis elegans*, whose six touch cells (ALML, ALMR, AVM, PLML, PLMR, PVM) are used to detect both internal and external forces. The intensity of the worm's withdrawal response from stimuli depends on the strength of the force. Mechanoreceptors also play a role in *C. elegans* reproduction. In order to facilitate mating, male *C. elegans* must utilize nine pairs of sensory rays to detect the position of a hermaphrodite's vulva. Genetic knockout males with faulty or absent rays cannot reproduce, emphasizing the importance of mechanosensation in *C. elegans*. Likewise, spiders belong to another invertebrate order (Araneae) with highly developed mechanosensory organs, including slit sensilla that detect vibrations, and tactile hairs, which enable spiders to navigate their webs (in web-building species) and locate prey (Mutai and Heller 2003).

## Conclusion

Impulses from touch, pressure, and sound waves travel along nerves to the central nervous system. Once the signal reaches the brain, the body can react to the stimulus. Thus, mechanoreceptors transduce mechanical energy from external stimuli into internal biologically useful neural information that the body uses to respond to stimuli.

Simple forms of mechanoreception have likely been present since the evolution of bacteria (approximately 3.5 bya). The ubiquity of mechanoreceptors across different domains of life suggests that they are of great evolutionary importance. Without mechanoreceptors, organisms would not have the ability to successfully navigate and/or respond to the outside world. This has been demonstrated by the high mortality rates seen in individuals with congenital analgesia, a disease characterized by nonfunctional nociceptors, which are specialized sensory neurons.

## Medial Entorhinal Area (MEA)

Pamela D. Rivière

University of California, San Diego, CA, USA

## Synonyms

[Medial entorhinal cortex \(MEC\)](#)

## Definition

Medial entorhinal area (MEA) refers to the medial subfield of the entorhinal cortex (EC) of rodents, bats, and a number of mammals with similarly structured brains. Its homologue in human and nonhuman primates is more accurately defined along the posterior, rather than medial, region of the entorhinal cortex. This brain area consists of a six-layered network of interconnected neurons whose patterns of electrical activity are thought to support spatial cognition.

## Introduction

To understand the role that the medial entorhinal area (MEA) plays in cognition and behavior,

investigators have attempted to identify the principles of structural and functional organization that govern the electrical activity of this brain region. Efforts toward characterizing the cellular organization, or microcircuitry, of the MEA have notably succeeded in identifying a range of morphologically distinct cell types and in describing how these neurons' cell bodies, dendrites, and axons are organized across the six layers of the MEA. Results from electrophysiological studies have additionally revealed neurons with markedly distinct patterns of electrical activity during behavior, leading investigators to functionally define a number of cell types in the MEA. To date, however, the relationship between morphologically and functionally defined cell types – as well as the contribution of these neurons to cognition and behavior – remains an open question.

## Current Knowledge

**Microcircuitry.** Neurons in the MEA are distributed along six cortical layers, designated I–VI, with larger numerals corresponding to layers located further from the surface of the brain. Superficial (I–III) and deep (IV–VI) layers are peppered to different degrees with a variety of morphologically distinct neurons that either excite or inhibit their postsynaptic targets.

The major known classes of excitatory neurons in the MEA are stellate and pyramidal cells. As their name suggests, **stellate cells** exhibit a roughly star-shaped appearance. The primary dendrites of these neurons emerge from the superficial portion of the cell body, or soma, and extend perpendicularly toward the surface of the brain. Dense arborization characterizes the length of the dendritic trunk. **Pyramidal cells'** somata and dendrites are similarly oriented, but they exhibit relatively sparse branching along the dendritic trunk, resulting in a more streamlined appearance that distinguishes these neurons from the starburst morphology of stellate arborization (Klink and Alonso 1997). The axons of stellate and pyramidal cells located in layers II and III project out of the MEA to form the perforant path, a dense array

of fibers that innervate each major subfield of the hippocampal formation (Witter et al. 2017). A subset of pyramidal cells found in layer V direct long-ranging axons toward various cortical and subcortical areas, while others innervate neurons in the superficial layers of the MEA and have been shown to particularly synapse onto layer III pyramidal cells (Kohler 1986; Witter et al. 2017).

Inhibitory neurons, which tend to suppress the electrical activity of their postsynaptic targets, can be further subdivided according to whether they issue local or long-ranging axonal fibers. An intricate network of locally projecting interneurons exerts inhibitory control over the excitatory cell population across the six layers of the MEA. This class of neurons includes **basket** and **chandelier cells** (Witter et al. 2017). These types of neuron vary in their somatic and dendritic morphology, yet they are more frequently differentiated by their axonal targets, as each type distinctly innervates either the soma or the initial axon segment, respectively, of excitatory cells located in the MEA. As far as the available evidence suggests, stellate and pyramidal cells do not directly innervate each other within the MEA. Instead, groups of interneurons provide direct synaptic contacts onto excitatory cells and coordinate their activity through a dense, recurrent inhibitory network (Couey et al. 2013; Witter et al. 2017). In contrast, the axons of long-ranging inhibitory neurons project out of the MEA to primarily innervate neurons in the hippocampus (Melzer et al. 2012), a finding that led to the realization that the entorhinal projection to the hippocampus is not exclusively excitatory.

Layers I and IV consist mainly of myelinated axonal fibers and glial cells and are only sparsely populated with neurons and their dendrites (Kohler 1986).

**Neural Correlates of Behavior.** Electrophysiological recordings carried out in awake, behaving animals have developed in parallel with the meticulous characterization of the microcircuitry of the MEA. While the bulk of these studies have been performed in rodents, a growing body of work has focused on data acquired from bats and nonhuman primates. Extracellular recordings in

these model species have overwhelmingly targeted the superficial layers of the MEA, largely due to their increased accessibility to recording electrodes relative to the deeper layers. According to results from various experiments, neurons located in layers II and III appear to exhibit strong spatial modulation that manifests as several complementary phenotypes, defined in the literature as **border**, **grid**, and **head-direction cells**. These patterns of electrical activity have lent credence to the hypothesis that functionally differentiable neurons may uniquely contribute to information processing in the MEA.

**Border cells**, which are thought to make up a small percentage of the neuronal population of the MEA, are neurons whose firing rates selectively increase as animals travel along segments of the physical boundaries of an environment (Solstad et al. 2008; Savelli and Knierim 2014). A larger proportion of MEA neurons, estimated at 50% in layer II (Sargolini et al. 2006), have been labeled **grid cells**. These neurons emit bursts of action potentials at spatial coordinates that coincide with the vertices of tessellated triangles (Hafting et al. 2005). The multiple, spatially distributed firing fields that each grid cell generates ultimately result in a gridded patterning of the surface area of an environment (Hafting et al. 2005). Rather than anchoring their activity to the boundaries of an enclosure, **head-direction cells** reflect vestibular and proprioceptive information by increasing their activity when an animal's head is oriented toward a preferred direction, regardless of the animal's allocentric position in the environment (Sargolini et al. 2006).

While the patterns of electrical activity used to define a given cell type are demonstrably robust, they have also been shown to be malleable. For example, some grid cells additionally exhibit head-direction modulation (Sargolini et al. 2006; Solstad et al. 2008), and a handful of neurons in several studies meet quantitative criteria for functional categorization as border and grid cells (Solstad et al. 2008). Moreover, Bonnevie et al. (2013) probed the impact of hippocampal inputs onto the MEA by pharmacologically suppressing

the CA1 region of the hippocampus and simultaneously recording electrical activity in the MEA. Over the period of hippocampal inactivation, grid cells simultaneously lost their grid fields and began exhibiting tuning to head direction, demonstrating the importance of available inputs in shaping MEA neuronal activity patterns during behavior. The ability of neurons to exhibit flexible patterns of activity suggests that there is no direct one-to-one mapping between morphology and functionality.

**Future Directions: Relating Structure to Function.** Neural activity depends on an intricate and highly dynamic interplay between the intrinsic properties of neurons and the connective structure in which they are embedded. Attempts to map neuronal morphology to function are ongoing (reviewed in Savelli and Knierim 2014). Additional efforts aim to identify the mechanisms whereby the organization of neuronal connections in the MEA fundamentally constrains and shapes the patterns of activity that its constituent cells manifest under a given set of circumstances. For instance, emerging data suggests that grid field generation may critically rely on the recurrent inhibitory circuitry that connects stellate and pyramidal cells in layers II and III (Couey et al. 2013). Moreover, computational simulations of the MEA network have provided a promising platform for experimenters to manipulate simulated physiological variables (e.g., neuronal morphology, network connectivity) and test the contributions of these variables to the resulting patterns of activity (Couey et al. 2013). Moving forward, the combination of empirical work and computational modeling will continue to elucidate the principles of structural and functional organization that ultimately shape the role of the MEA in cognition and behavior.

## Medial Striatum

Genevra Hart and Bernard Balleine

School of Psychology, University of New South Wales, Sydney, Australia

## Synonyms

[Associative striatum](#); [Caudate nucleus](#); [Dorsomedial neostriatum](#); [Dorsomedial striate nucleus](#)

The dorsal striatum is composed of two sub-regions, the dorsomedial and dorsolateral striatum, that, although thought to be generally similar in terms of their internal microcircuits and cell types, are now known to differ in a number of important ways. Among these is their connectivity; recent evidence suggests that, whereas the cortical inputs to the dorsolateral striatum are largely from sensorimotor cortices, the dorsomedial striatum receives the most heterogeneous cortical input of all striatal regions (Hunnicutt et al. 2016), and additionally receives glutamatergic inputs from the thalamus and basolateral amygdala. Both regions receive rich dopaminergic inputs from the substantia nigra pars compacta. Importantly, these distinct inputs have been found to play quite distinct functional roles in learning and behavior; whereas the dorsomedial striatum is involved in behavioral flexibility generally and in goal-directed action in particular, the dorsolateral striatum has variously been linked to relatively inflexible or automatic skilled motor movements and to the formation or “chunking” of action sequences or, more generally, to the control of habitual actions. Taken together, therefore, the medial and lateral regions of the dorsal striatum are currently thought to mediate two of the primary forms of action control composing the adaptive behavior of animals; i.e., goal-directed actions and habits.

## Background

Classical views of striatal function centered on its role in motor control, according to which striatal regions gathered information from widespread cortical areas and funneled this information through the basal ganglia and ventrolateral thalamus to the primary motor cortex to control movement (e.g., Kemp and Powell 1971). Alexander et al. (1986) were among the first to observe that the basal ganglia anatomy only superficially accorded with this view and went on to describe multiple parallel corticostriatal feedback loops, involving both motor and nonmotor regions of the cortex, which they felt could enable striatal involvement in a broad range of movement typographies. The authors reviewed the results of tracing studies and identified five parallel corticostriatal loops, originating from distinct cortical regions; skeletomotor, oculomotor, dorsolateral prefrontal, lateral orbitofrontal, and anterior cingulate (Alexander et al. 1986). Subsequent neuroanatomical and functional interrogation of striatal circuitry has refined the descriptions of these circuits and the involvement of other cortical and limbic regions, such as the temporal cortex (Middleton and Strick 1996) and the amygdala (Kelley et al. 1982), and has suggested that, rather than supporting heterogeneous motor movements, these parallel loops actually mediate heterogeneous forms of behavioral control process (Balleine and O'Doherty 2010).

## Anatomy

The dorsomedial striatum contains two populations of spiny projection neurons, which together make up 95% of all striatal neurons. Approximately half of the medial striatal projection neurons are striatonigral neurons and are the source of a direct monosynaptic projection to the substantia nigra pars reticulata (SNr). These direct pathway neurons preferentially express the neuropeptides substance P and dynorphin and express the dopamine D1 receptor. The remaining spiny projection neurons in the dorsomedial striatum also project to the SNr indirectly via a

multisynaptic pathway within the basal ganglia that includes the external part of the globus pallidus (GPe) and the subthalamic nucleus. These indirect pathway neurons preferentially express enkephalin, the adenosine A<sub>2A</sub> receptor and the dopamine D2 receptor. The remaining 5% of neurons are made up of a number of different interneurons, including the giant aspiny cholinergic interneurons that modulate striatal output neurons through the release of acetylcholine, and other interneurons that express somatostatin, neuropeptide Y, or nitric oxide synthase and regulate striatal output through the release of gamma-aminobutyric acid (GABA).

## Function

**Rodent** The anterior region of the dorsomedial striatum (aDMS) in the rat extends from approximately 2.76 mm anterior to bregma to the end of the ventral striatum, approximately 0.48 mm anterior to bregma. The aDMS is involved in cue-guided behavioral flexibility (Ragozzino et al. 2002), which is thought to be regulated by cholinergic activity (Ragozzino et al. 2009). Cortical projections from the prelimbic region of the medial prefrontal cortex to the aDMS have been associated with regulating cost-benefit choice behavior (Friedman et al. 2015). The anteriomedial quadrant of the DMS is involved in feeding; surges in enkephalin occur during feeding, and increases in mu-opioid receptor signaling induce feeding behavior (DiFeliceantonio et al. 2012). In contrast, the posterior dorsomedial striatum (pDMS), beginning around 0.24 mm anterior to bregma, has been implicated in several aspects of goal-directed learning and decision making. The pDMS is necessary for learning the specific action-outcome associations required for goal-directed learning and for the performance of goal-directed actions following learning (Yin et al. 2005a). This learning relies on N-methyl-D-aspartate (NMDA) receptors in the pDMS (Yin et al. 2005b) and phosphorylation of mitogen-activated protein kinase (MAPK), thought to occur as a result of coactivation of NMDA receptors and D1 receptors (Shiflett et al. 2010). The

glutamatergic input to the pDMS from the pre-limbic cortex is thought to be necessary for acquiring the specific action-outcome association during goal-directed learning (Hart and Balleine 2016), whereas the glutamatergic input from the parafascicular thalamus to cholinergic interneurons in the pDMS is not required for initial learning, but necessary for updating new action-outcome learning (Bradfield et al. 2013). The glutamatergic input from the BLA to the pDMS is necessary for goal-directed learning and performance (Corbit et al. 2013); however, this input is thought to contribute information about outcome value, embedded within the sensory-specific properties of the outcome (Balleine and Killcross 2006; Fig. 1).

**Humans** Homologies between rodent and human striatum have been drawn along more general lines, suggesting that the dorsomedial striatum in rodents is homologous to the caudate nucleus in humans (Balleine and O'Doherty 2010; Balleine et al. 2007). From this perspective, decision making in humans reflects much the same division as observed in rodents; flexible, reward-related action control involves the more medial caudate whereas relatively inflexible, habitual actions involve the more lateral putamen. For example, fMRI studies have shown that there is an increase in activity in the anterior caudate when the contingency between an instrumental response and reward is high (Tanaka et al. 2008), and similar to the dissociation between the rodent aDMS and pDMS, the activity in the posterior

caudate is associated with detecting noncontingent reward delivery (Liljeholm et al. 2011). There are also homologies in the role of the cortical input to the striatum in rodents and humans; the ventromedial prefrontal cortex in humans is considered homologous to the prelimbic cortex in rats (Balleine and O'Doherty 2010), and as with rats, this pathway has likewise been implicated in goal-directed actions, whereby the strength of input to the caudate predicts individual differences in the degree of flexible goal-directed action demonstrated by people (de Wit et al. 2012).

## Dysfunction

Given its intrinsic structure and its known functions, it is perhaps unsurprising that the dorsomedial striatum has been closely linked to executive functions and that, as with its afferent regions in frontal cortex, changes in the activity of this region, whether induced by stroke; neurodegenerative conditions, such as Parkinson's disease dementia; psychiatric conditions such as schizophrenia, major depression, or addiction; and even normal aging have been found to result in a common set of symptoms called collectively dysexecutive syndrome. The symptoms of this syndrome involve cognitive, affective, and behavioral changes reflecting increased inflexibility; cognitive rigidity and emotional and behavioral disinhibition. Interestingly, this is similar to that observed with habitual action control, in which

M

### Medial Striatum,

**Fig. 1** Sagittal representation of the rat brain showing primary input pathways to the dorsomedial striatum. *aDMS*, anterior dorsomedial striatum; *pDMS*, posterior dorsomedial striatum; *BLA*, basolateral amygdala; *SNc*, substantia nigra pars compacta

performance is stimulus bound, motivated by general activation and associated with behavioral repetition. In essence, many disorders are partially characterized by a loss of goal-directed action control and the intrusion of habits. There is some evidence in clinical populations that some aspects of dysexecutive syndrome may be the result of reduced activity in the caudate; for example, patients with schizophrenia show intact sensitivity to changes in outcome value, but deficits in using those changes to flexibly alter choice, and this deficit is associated with a reduction in activity in the anterior caudate nucleus (Morris et al. 2015). Adolescents with major depressive disorder show reduced caudate activity, relative to healthy controls, during reward anticipation and reward outcome (Forbes et al. 2009). Dopamine release in the caudate and putamen is suppressed by drug-associated cues in drug addicts, and the magnitude of dopamine reduction is associated with cravings (Volkow et al. 2006), and patients with Parkinson's disease dementia show a significant reduction in caudate activity during a working memory task, relative to patients with Parkinson's disease without dementia (Lewis et al. 2003).

## Medial Temporal Lobe

Irene Alonso

Department of Psychology, University of Oviedo, Oviedo, Spain

## Structure and Connectivity

The medial temporal lobe (MTL) corresponds to the amygdala and the fifth temporal convolution of the human temporal lobe. The MTL cortex can be subdivided in the hippocampal formation and the surrounding cortex, the parahippocampal gyrus. The latter includes the entorhinal cortex, perirhinal cortex, and parahippocampal cortex (Squire and Zola-Morgan 1991; Zola-Morgan and Squire 1993). Important bidirectional pathways are established between high-order associative areas of the cortex and the MTL (Lavenex and Amaral 2000; Qin et al. 2016). The perirhinal cortex receives more prominent projections from unimodal associative areas such as the inferior temporal cortex and has efferents toward the lateral entorhinal cortex. The parahippocampal cortex receives inputs from multimodal associative areas such as the posterior parietal lobe and projects toward the medial entorhinal cortex. These two routes, commonly referred in the literature as the “what” and the “when” streams, finally converge in the hippocampus (Eichenbaum and Lipton 2008).

The hippocampal formation is a complex region with different cytoarchitectonical subregions including the subiculum, the hippocampus (also referred as the hippocampus proper or the Cornu Ammonis), and the dentate gyrus (Insausti and Amaral 2003). This structure has great synaptic plasticity properties, and it is the main site of adult neurogenesis in the brain (see chapter on the “► Hippocampus”). The hippocampus can be considered an information hub at the top of the hierarchy of the MTL system. Information can flow in and out the hippocampus from two main

routes: (a) via subiculum (mediated by the entorhinal cortex) (Lavenex and Amaral 2000) and (b) via fornix (Aggleton et al. 2010). After hippocampal processing, information can be then output back to the parahippocampal gyrus through the subiculum and from there to the cortex. The fornix connects the hippocampus with subcortical areas including septal nuclei (particularly nucleus basalis of Meynert), mammillary bodies, anterior thalamic nuclei, ventral striatum, ventral tegmental area, locus coeruleus, and raphe nuclei. Additional direct afferents are received from the amygdala, which also has a connection to the hippocampus through the entorhinal cortex. Both hippocampi are connected through the commissure of fornix (also called hippocampal commissure), and the anterior commissure connects both medial temporal lobes.

Taking all together, these circuits and the particular cytoarchitectonical characteristics of the MTL allow establishing feedback and feedforward connections with the cortex, which are essential for memory.

## The Role of MTL on Memory Processes

The pioneering work by Brenda Milner and colleagues evaluating patients with lesions in the MTL, including the iconic case of patient Henry Molaison (1926–2008), opened avenues for the investigation of the various aspects of memory that are causally linked to this area (Scoville and Milner 1957). H. M. had followed bilateral MTL removal for the relief of intractable temporal lobe epilepsy at the age of 27. Due to this treatment, he developed a severe amnesia. H. M. was unable to learn new information or form new memories – a condition called *anterograde amnesia*. Additionally, access to memories of events and facts occurring prior to the surgery was impaired to some extent – a condition called *retrograde amnesia*. This retrospective memory retrieval deficit occurred in a temporally graded manner, such that he was unable to recall almost anything from the 3 years prior to the surgery, but he was able to retrieve older memories. Such chronological pattern of impairment for autobiographical

memory following MTL insult is known as the Ribot's Law (for a review, see Frankland and Bontempi 2005). Strikingly, general intellectual and perceptual functions were preserved as well as working memory, procedural memory, and *priming* (an implicit memory facilitation effect, whereby the exposure to certain stimuli affects the later response to other stimuli or tasks).

The publication of H. M.'s case, as well as other MTL lesion studies that followed, established the causal role of the MTL in *declarative memory* (explicit and conscious memory for facts and events). However, these studies were limited since lesions extended broadly to the anterior temporal lobe. Hence, such evidence did not allow isolating the specific contribution of each MTL structure. This fact prompted the development of animal models, followed by the use of neuroimaging techniques, which shed light on the functional properties of this region and fostered the distinction between different memory systems.

Soon it was established that the memory deficits observed were related to the hippocampus and the surrounding parahippocampal gyrus, which will be hence referred to as the MTL memory system, excluding the amygdala and the lateral anterior temporal lobe (Squire and Zola-Morgan 1991; Zola-Morgan et al. 1991).

Today, the role of the MTL in long-term *episodic memory* (explicit encoding, consolidation, and recollection of experienced events including contextual details such as where, when, why, or with whom) is well established. For many years, a dominant view of memory recognition proposed subdividing recognition in two qualitatively distinct processes: familiarity and recollection (for a review see Yonelinas 2002). On the one hand, *familiarity* is a distributed process that follows the rules of signal detection, targeting a sense of knowing or having had previously experienced something. On the other hand, *recollection* is defined as an all-or-nothing process that may require the identification of details of an object or scene. Familiarity, recollection, and novelty processes were suggested to depend in different structures within the MTL (Daselaar et al. 2006). Accumulated evidence has shown that while the

hippocampus is engaged in processing the details that lead to recollection, the surrounding perirhinal and parahippocampal cortex can support familiarity (for items and context, respectively) with certain independence of the hippocampus.

More recently, the growing interest on describing the particular elements that differentiate MTL structures' roles has led to a new approach. It considers that the core function performed by the MTL is the establishment of arbitrary associations, relational processing, or binding. Instead of building up on the psychological distinction between familiarity and recollection, researchers have begun to focus on the qualitative differentiation of MTL structures and a functional specialization dependent on the kind processed information (for a review, see Eichenbaum et al. 2012). One of the most influencing MTL function models in this vein is the Binding Item and Context (BIC) model (Davachi 2006; Diana et al. 2007; Eichenbaum et al. 2007).

Based on neuropsychological and neuroimaging findings, the BIC model stresses the importance of binding during both encoding (Davachi 2006) and retrieval (Diana et al. 2007). According to this model, the perirhinal cortex supports the encoding of items and item features (intra-item associations) and plays a role in certain complex perceptual tasks (for a review, see Graham et al. 2010). On the other hand, the parahippocampal cortex supports the processing of the context in which items are presented. This context can include spatial (the "where"), temporal (the "when"), or even emotional information. All this information is finally transmitted through the entorhinal cortex into the hippocampus, which is the key structure that binds items and context across time and space into a single memory trace (inter-item associations).

## Spatial Navigation

Nevertheless, many different aspects and specifics of MTL function are still under debate. The exclusively long-term memory function of the MTL has been challenged. For instance, it has been suggested that the region also plays an important

role in short-term memory (Ranganath and Blumenfeld 2005) and perception (for supporting and contrasting views see, Baxter 2009; Suzuki 2009).

One of the most relevant debates rises from specifying the main hippocampal function as spatial navigation in contrast to declarative memory (Eichenbaum and Cohen 2014). A long tradition in the rodent literature has focus on the spatial navigation function of the MTL including in the human (for a review see, Moser et al. 2008) since the discovery of place cells (in the hippocampus and parahippocampal cortex) (O'Keefe and Dostrovsky 1971) and grid cells (in the entorhinal cortex) (Fyhn et al. 2004). *Place cells* are neurons that fire when the animal is positioned at a specific spatial location. *Grid cells* are neurons that provide a position-in-space signal such as a cognitive representation of the space. From this perspective, the MTL has a main role for both spatial memory and spatial navigation (Sanders et al. 2015).

More recently, neurons that fire at particular moments within a relevant time period have been identified in the hippocampus, namely, *time cells* (for a review, see Eichenbaum 2014). This has led some authors to suggest that the ultimate goal of the MTL may not be specific to the spatial navigation per se but rather reflect the integration and encoding of multiple details of the spatiotemporal context and the content of a given event that allows its differentiation from other events, whether they are pathways, sequences, or autobiographical memories (Eichenbaum and Lipton 2008; Eichenbaum et al. 2012).

## Amygdala

From an anatomical viewpoint, the amygdala is part of the medial temporal lobe. However, this independent nucleus is often excluded in most studies addressing the MTL function, which focus on the medial temporal lobe cortex (Squire et al. 2004). This is due in part because the amygdala does not directly contribute to episodic memory or spatial navigation. Instead, the amygdala has received greater attention for its role in emotional processing, fear conditioning, and

modulation of memory consolidation (LaBar and Cabeza 2006). More information on the function of this structure can be consulted in the appropriate chapter.

## Synonyms

Myelencephalon

## Definition

The medulla is a funnel-shaped structure located between the pons and spinal cord. It is responsible for regulating the heart rate, arterial blood pressure, autonomic functions, and transmission of sensory and motor signals between the spinal cord and the cortex of the brain.

## Introduction

The medulla or medulla oblongata, synonymously known as myelencephalon, is a stem-like, funnel-shaped structure and is located posterior to the midbrain. It extends from the foramen magnum up to the pons-medullary junction [as shown in Fig. 1] (Haines 2018).

The medulla regulates the body's motor function by ascending and descending fiber tracts that pass forward and backward through the spinal cord by traversing the medulla. The medulla also contains neuronal cell groups extending from medullary reticular formation, which play a fundamental role in regulating visceral sensory processing, heart activity, gastrointestinal, and other physiological functions, thereby maintaining homeostasis of the body (Verberne 2014). Medulla is present among different animal species (Fig. 2). Lamprey and hagfish possess a fully developed medulla (Nishizawa et al. 1988), which is thought to be evolved around approximately 505 million years ago (Haycock 2011).

## Development

During the initial stages of embryonic development, medullary neurons emerge from the caudal section of the neural tube known as rhombencephalon, which further differentiates into two structures called metencephalon (forming the pons and cerebellum) and myelencephalon (forming the medulla), as shown in Fig. 3 (Verberne 2014).

The basal plate and alar plate during the development phase differentiate into **somatic afferent [SA]**, **somatic efferent [SE]**, **visceral afferent [VA]**, and **visceral efferent [VE] nuclei** (Fig. 4).

The basal plate gives rise to the **hypoglossal nucleus [SE]**, the inferior **salivatory nucleus [VE]**, the **dorsal motor vagal nucleus [VE]**, and the **nucleus ambiguus [SE]**.

Furthermore, the alar plate forms the cranial nerve nuclei such as the **vestibular nuclei [SA]**, the **cochlear nuclei [SA]**, and the **spinal trigeminal nucleus [SA]**, along with the **solitary nucleus [VA]** (Haines 2018).

## Anatomical Structure

### External Anatomical Features

#### Anterior Medulla

The anterior portion of the medulla can be distinguished by a median fissure (anterior) that has two

**Medulla Oblongata,**

longitudinal ridges located adjacent to the inferior olivary eminence and the pyramids. The pyramids emerge from the basilar pons and stretch caudally toward the pyramidal decussation, and about 90% of these fibers traverse through the midline. Most of these fibers have their origin in the motor cortex as corticospinal fibers; hence, this crossing is also

known as motor decussation. The hypoglossal nerve leaves the medulla from a deep groove present between the pyramid and olive, known as the preolivary sulcus. In addition, the abducens nerve surfaces at the pons-medullary junction, in line with the rootlet hypoglossal nerve (Haines 2018).

**Medulla Oblongata, Fig. 4** Cross section through the developing medulla: **a)** early stage, **b)** later stage

**Lateral Medulla**

The lateral segment of the medulla has a deep groove, known as the postolivary sulcus. It is located medially between two structures, the restiform body and the inferior olivary nucleus. Cranial nerves, for example, the vagus and glossopharyngeal nerves, emerge from this

region. In comparison, the facial and vestibulo-cochlear nerves arise from the posterolateral medulla. However, the structures that are served by the accessory nerve do not have any projections from the medulla (Haines 2018).

The brain and the fourth ventricle contract to form the central canal of the spinal cord at a point

**Medulla Oblongata, Fig. 5** Transverse section of the medulla at the level of the caudal medulla showing the fasciculus, tracts, and nucleus

called obex. Anterior to this point lies the restiform body, whereas the trigeminal tubercle (tuberculum cinereum) is located posteriorly (Haines 2018).

#### Posterior Medulla

The posterior segment of the medulla is characterized by the cuneate fasciculi and gracile nucleus (Fig. 5) located caudal to the obex and their respective tubercles (Fig. 5). Anterior to these tubercles lies a protruding elevation on the posterolateral region of the medulla, called the restiform body. This structure continues to elevate up to the pons-medullary junction and holds a range of cerebellar afferent fibers. At the pons-medulla junction, the restiform body joins with a much smaller juxtarestiform bundle to form the inferior cerebellar peduncle (Haines 2018).

#### Internal Anatomy

The internal anatomy of the medulla is commonly studied at the following levels:

##### Spinal Cord-Medulla Transition

The transition between the medulla and spinal cord takes place at the caudal level of pyramidal

decussation. The gray matter of the spinal cord is replaced with motor decussation, substantia gelatinosa, and posterolateral tract fused into the spinal trigeminal tract and nucleus, and the central gray matter enlarges (Haines 2018).

The central canal of the spinal cord extends until the caudal half portion and then expands into a cavity of the fourth ventricle, in the rostral half of the medulla (Snell 2010).

##### Level of Decussation of Pyramids

At the level of pyramidal decussation (motor decussation), approximately 90% of the corticospinal fibers pass through the anterior midline and continue down to the spinal cord as the lateral corticospinal tract. Posterior to the central gray matter, the gracile and cuneate nuclei first appear in their respective fasciculi, collectively known as posterior columns.

Laterally, the spinal trigeminal tract appears as the trigeminal tubercle or tuberculum cinereum on the surface of the medulla.

The caudal segment of medulla contains the remnants of medial motor cell column of C1, nucleus ambiguus, tectobulbospinal system (Fig. 5), and medial longitudinal fasciculus,

whereas remnants of the medial motor cell column of C1 and accessory column can be seen at the spinal cord medullary junction, but they do not innervate the medulla (Haines 2018).

#### Level of the Sensory Decussation

At this level, a major ascending sensory pathway traverses through the midline, known as posterior column-medial lemniscus, and because of which, it is known as sensory decussation. The posterior columns are mainly replaced by the gracile and cuneate nuclei, onto which the fibers responsible for conveying vibratory and tactile sensations from the upper and lower parts of the body terminate.

The axons from these nuclei traverse anteromedially to form the internal arcuate fibers and then decussates in a contralateral manner to form the medial lemniscus. Axons of the gracile nucleus and cuneate nucleus convey information coming from the lower and upper extremities to the anterior and posterior regions of the medial lemniscus (Haines 2018).

In the anterolateral region of the medulla, the vestibulospinal, spinocerebellar, and rubrospinal tracts are situated. Lateral to the internal arcuate fibers lies the nucleus of the spinal tract of the trigeminal nerve, and collectively, they are known as spinal lemniscus (Snell 2010).

#### Level of the Olivary Nucleus

A transverse section through this region reveals the floor of the fourth ventricle. At this level, the amount of gray matter increases due to the presence of the vestibulocochlear, glossopharyngeal, hypoglossal nerve, vagus, accessory, olivary nuclear complex, and arcuate nuclei (Snell 2010).

#### • Olivary Nuclear Complex

The complex contains nuclei-like inferior olivary nucleus and dorsal and medial accessory olivary nuclei, out of which the inferior olivary nucleus is the largest. Here, the medially facing gray matter is present in the shape of a crumpled bag (Fig. 5), which is responsible for the protruded structure called the olive, located on the surface of the medulla (Snell 2010).

#### • Vestibulocochlear Nuclei

The vestibular nuclear complex is composed of the following nuclei: (1) inferior vestibular nucleus, (2) superior vestibular nucleus, (3) lateral vestibular nucleus, and (4) medial vestibular nucleus.

There are other two nuclei: the anterior cochlear nucleus located on the anterolateral portion of the inferior cerebellar peduncle and the posterior cochlear nucleus on the posterior region of the peduncle and lateral to the floor of the fourth ventricle (Snell 2010).

#### • The Nucleus Ambiguus

It consists of large motor neurons located deep within the reticular formation (Fig. 5). Nerve fibers emerging from this nucleus synapse with the vagus, glossopharyngeal, and cranial part of the accessory nerve and are dispersed to the voluntary skeletal muscle (Snell 2010).

#### Rostral Medulla and Pons-Medulla Junction

The structures that occupy the position at the central portion of the medulla oblongata continue at same locations in the rostral medulla. However, structure like the inferior salivatory nucleus and prepositus (hypoglossal) nucleus appears (Haines 2018).

#### Ascending Tracts

##### Dorsal Column Tracts

The tracts of dorsal column or medial lemniscal system carries the sensory information for delicate touch, vibration, positioning, and point discrimination from skins and joints.

The medial lemniscal system consists of ascending axons of cuneate and gracile fasciculi, which receives the sensory input from the upper and lower of the body and terminate in the cuneate and gracile nucleus, traversing through the medial lemniscus and relaying the information to the thalamus and ultimately to the somatosensory cortex (Verberne 2014).

##### Spinothalamic Tracts

Spinothalamic tracts originate from the neurons of the spinal dorsal column, receiving its sensory

input from afferent fibers of Lissauer's tract of the spinal cord. It has two subdivisions; the lateral branch carries temperature and pain information, while the anterior part conveys the information about fine touch (Verberne 2014).

#### Spinoreticular Tracts

The axons of spinoreticular tract convey the information about intense pain and arise from the ventrolateral spinal cord neurons and terminate onto neurons of the rostral ventrolateral medulla and midline medullary raphe (Verberne 2014).

#### Spinal Trigeminal Tract

The trigeminal nerve is responsible for the conduction of sensory information from the nose, face, and mouth to the brain. The medulla receives one-third projection from the caudal segment of the spinal trigeminal nucleus (Fig. 5), terminating in the subnucleus caudalis, and conveys the information about pain and temperature (Verberne 2014).

#### Spinocerebellar Tracts

Spinocerebellar tracts pass through the lateral medulla into the cerebellum via cerebellar peduncles. This tract transmits the information from tendon organs, muscle spindles, pressure, baroreceptors, and control movement (Verberne 2014).

#### Cranial Nerve and Nerve Nuclei

The medullary structure contains the fibers and nucleus of cranial nerves such as facial nerve, glossopharyngeal nerve, vagus nerve, accessory nerve, and hypoglossal nerve that originate and project from the medulla (Verberne 2014).

**Facial Nerve** The facial nerve (cranial nerve IX) originates from the anterior surface of the pons-medullary junction and has motor, sensory and parasympathetic nuclei (Snell 2010).

The motor segment of the facial nerve supplies the muscles of the scalp, face, stylohyoid muscle, and digastric muscle through somatic motor axons, responsible for voluntary muscle control and facial expressions as its motor neurons project to and control the muscles of the lips, cheeks, and forehead (Snell 2010).

The taste fibers originating from the floor of the mouth, anterior two-third of the tongue, and palate innervate the sensory nuclei and are responsible for the sensation of taste (Snell 2010; Verberne 2014).

The parasympathetic nuclei is located posterior to the motor nucleus and consist of lacrimal and superior salivatory nuclei. Both nuclei receive their projections from hypothalamus. The lacrimal nuclei receive information about emotional response, reflex lacrimation through the trigeminal nerve and the superior salivatory receives information about taste from the mouth cavity through the nucleus of the solitary tract (Snell 2010).

**Glossopharyngeal Nerve** The glossopharyngeal nerve (cranial nerve IX) exits the anterolateral surface of rostral medulla as a string of rootlets, in a fissure located in between the olive and the inferior cerebellar peduncle. The glossopharyngeal nerve has three nuclei: (1) the main motor nucleus, (2) the sensory nucleus and (3) the parasympathetic nucleus.

The motor nucleus is located deep within the reticular formation of the medulla and emerges from the anterior end of nucleus ambiguus. The stylopharyngeus muscle is responsible for the elevation of laryngeal and pharyngeal muscles that receive its motor input from the efferent fibers of the glossopharyngeal nerve.

The sensory nucleus emerges as a part of the nucleus of tractus solitarius and receives its input from the carotid sinus (responsible for the control of arterial blood pressure), pharynx, and caudal one-third of the tongue (responsible for taste) (Snell 2010).

The parasympathetic nucleus receives its afferent projections from the hypothalamus through the autonomic pathways, which are believed to receive the olfactory information via reticular formation.

The preganglionic efferent parasympathetic fibers extend up to the otic ganglion via the lesser petrosal nerve, tympanic branch of the glossopharyngeal nerve, and the tympanic plexus. The postganglionic fibers progress towards the parotid salivary gland.

**Vagus Nerve** The vagus nerve exits the anterolateral surface of the rostral medulla as rootlets, from the middle of the olive and cerebellar peduncle.

The vagus nerve also has both motor and sensory nuclei:

The motor nucleus is located deep within the reticular formation of the medulla and emerges from the nucleus ambiguus.

The parasympathetic nucleus of the vagus nerve is a subdivision of the motor segment that receives the afferent projections from the hypothalamus and glossopharyngeal nerve. The efferent fiber innervates involuntary muscles of the heart (heart rate), bronchi, stomach, small intestine, and large intestine and extends to the distal one-third of the transverse colon (peristalsis).

The sensory nucleus emerges as a caudal portion of the nucleus of the tractus solitarius and the incoming afferent input that enters the brain stem and terminates in the spinal nucleus of the trigeminal nerve. The sensory input conveys information from mechanoreceptors; chemoreceptors of the GI tract, lungs, and heart; and hepatic glucoreceptors (Snell 2010; Verberne 2014).

**Accessory Nerve** The accessory nerve (cranial nerve XI) is a motor nerve formed by the fusion of a spinal root and a cranial root.

The axons of nerve cells lying in nucleus ambiguus form the cranial root. The motor fibers emerge anteriorly from the medulla between the inferior and olive cerebellar peduncle. The spinal root is formed from the axons of nerve cells lying in the spinal nucleus, located in the gray column of the upper five cervical segments of the spinal cord.

The accessory nerve is responsible for the voluntary movement of the larynx, pharynx, and trapezius muscle (Snell 2010).

**Hypoglossal Nerve** The hypoglossal nerve (cranial nerve XII) is a motor nerve that emerges anteriorly from the medulla, innervating the extrinsic styloglossus, genioglossus, hyoglossus, and intrinsic muscles of the tongue. It is responsible for the voluntary control of the shape and movement of the tongue (Snell 2010).

### Spinal Trigeminal Tract

The sensory input from mouth, face, and nose is carried to the nervous system by the afferent cell bodies of trigeminal nerve found within the trigeminal ganglion.

The neurons of trigeminal ganglion enter the brainstem at the pons level and have two main components, (1) principal sensory nucleus and (2) spinal trigeminal nucleus, situated in the lateral medulla and the posterior one-third in subnucleus caudalis of the medulla (Verberne 2014).

### Descending Tracts

Most of the axonal bundles pass through the medulla in a rostrocaudal manner. These bundles may not synapse with the medullary region, but a traumatic lesion can significantly impair the functions for which they are responsible (Verberne 2014).

### Corticospinal Tract

Corticospinal tracts are responsible for conducting motor signals from the premotor and precentral motor cortex to the spinal cord descending through the medullary pyramids in the medulla and controlling the body's voluntary movements (Verberne 2014).

### Corticobulbar Tract

The axons of the corticobulbar pathway travel through the primary motor cortex; project into the nucleus of cranial nerve such as hypoglossal, ambiguus, facial, and trigeminal nucleus; and control muscles of the face, head, and tongue regions. The facial, ambiguus, and trigeminal nuclei receive the cerebral cortex's input in an ipsilateral manner (Verberne 2014).

### Medial Forebrain Bundle

It contains the axons from neurons projecting to and from the hypothalamus and the other structures. They also contain the neurons from the paraventricular hypothalamic nucleus that projects to the dorsal medulla such as the dorsal motor nucleus of vagus and solitary tract (Verberne 2014).

### Vestibulospinal Tract

The vestibulospinal tract axons originate from the lateral and medial vestibular nucleus into the spinal cord's white matter. The vestibulospinal pathway is responsible for controlling antigravity muscles and facilitates the rapid movements in response to the change in body position (Verberne 2014).

### Rubrospinal Tract

The fibers of rubrospinal tract are responsible for the somatic motor function, originate from the midbrain's contralateral red nucleus, and go down into the spinal cord via lateral medulla (Verberne 2014).

### Reticulospinal Tract

The reticulospinal tract emerges from the midbrain, medullary reticular formation, and pontine and plunges into the gray matter of the spinal cord in both contralateral and ipsilateral manner. The axons projecting to these structures originate from the ventral midline raphe neurons and modulate the somatosensory transmission, e.g., pain, and some of them are responsible for the production of the neurotransmitter serotonin (Verberne 2014).

### Tectospinal Tract

The axons of tectospinal tract arise from the neuronal cell bodies of tectum and superior colliculus descending through the medulla and are responsible for rotatory movement of the head in response to the auditory and visual stimuli (Verberne 2014).

### Medial Longitudinal Fasciculus

It is responsible for carrying out the head and eye movements and consists of neurons found in vestibular nuclei, where it forms an additional fiber tract that descends near the tectospinal tract (Verberne 2014).

## Vasculature

The medulla is supplied with two main vertebral arteries, the anterior spinal artery and the posterior inferior cerebellar artery (PICA), and an

additional artery known as the posterior spinal artery, a subdivision of PICA.

The anterior spinal artery serves all the medial structures of the medulla, including the hypoglossal nucleus and roots, the medial lemniscus, and the pyramid through its innervating branches.

The posterior spinal artery serves the posterior region caudal to the obex. Significant structures in this area include the spinal trigeminal tract, nucleus, and posterior column (gracile and cuneate) nuclei.

The branches of PICA serve the entire posterolateral medulla, located rostrally to the obex, including the anterolateral system, vestibular nuclei, spinal trigeminal tract and nucleus, nucleus ambiguus, solitary tract, and nucleus (Fig. 5).

Apart from the medulla, PICA also serves the fourth ventricle's choroid plexus, and the anterior inferior cerebellar artery serves structures like the cochlear nuclei, pons-medulla junction, and a small adjacent part of the restiform body (Haines 2018).

## Function

### Physiological Functions

#### • Arousal and Nociception

The medulla is a major site for the processing of pain (nociceptive), where neurons within raphe magnus nucleus play a fundamental role by controlling the activity of nociceptive ascending pathway and, in turn, are controlled by neurons in the midbrain periaqueductal gray area.

Apart from pain processing, the raphe magnus nucleus controls a range of motor and sensory functions, including sympathetic vasomotor control, some aspects of sexual organ function, nociception, and thermoregulation.

The sensory neurons of the solitary tract nucleus are organized in a topographical manner so that its rostral segment receives significant gustatory input. In comparison, the intermediate and caudal segments receive general visceral and respiratory inputs. These neurons not only synapse with intramedullary neurons but significantly contribute to the ascending projection as well (Verberne 2014).

- **Eating and Digestion**

The medulla is implicated in the process of digestion. Various signals such as hunger, visual stimuli, and nutrients in intestinal lumen trigger responses like salivation, changes in gastrointestinal blood flow, motility, and release of cholecystokinin (CCK) from endocrine cells via afferent fibers of the vagus nerve, which synapse in the nucleus of solitary tract of the medulla. These signals are then conveyed to the hypothalamus by ascending pathways, where they further regulate the groups of neurons that control food consumption (Verberne 2014).

- **Taste**

Gustatory (taste) signals perceived by the taste buds are transmitted to the nucleus of the solitary tract by primary efferent fibers. These signals are relayed to higher regions such as the somatosensory thalamus and parabrachial nucleus, which in turn transmits it to the gustatory region of the postcentral gyrus and insular cortex (Verberne 2014).

- **Salivation**

The neurons that control the production of saliva, by stimulating salivary glands (sublingual, lingual, and submandibular glands), are in the salivatory nucleus near the dorsal pons-medullary junction. These neurons also control the secretion from lacrimal, nasal, and palatine glands (Verberne 2014).

- **Vestibular Function**

The vestibular system perpetuates functions like posture, body stance, and movements of the head and eye in response to vestibular signals. The inferior olivary complex located in the ventral part of the medulla directs the fiber inputs from components of the vestibular system via the olivocerebellar tract to the Purkinje cells of the cerebellum (Verberne 2014).

- **Cardiovascular Regulation**

The neuronal networks within the medulla provide negative feedback by relaying the afferent information to the brain through cranial nerves, to regulate the homeostatic bodily function of the body such as arterial baroreceptor reflex, maintenance of the heart rate, and sympathetic vasomotor discharge.

The neurons of rostral ventrolateral medulla are implicated in several processes such as cardiovascular reflexes, glucose homeostasis, and epinephrine secretion and are targeted by the antihypertensive drugs to exert its effect by inhibiting it (Verberne 2014).

- **Respiration**

The Bötzing and pre-Bötzing complexes found in the rostral ventrolateral medulla and the rostral-caudal ventral respiratory groups of neurons are responsible for the generation of rhythmic respiratory activity (timing and depth of respiration) and are also known as a central respiratory generator.

The central respiratory generator regulates the timing and depth of respiration, and its function remains unaltered even under the influence of anesthesia, except in case of deep anesthesia or overdose of drugs, which causes respiratory arrest (Verberne 2014).

## **Disorders**

- **Wallenberg Syndrome**

The Wallenberg syndrome or lateral medullary syndrome is characterized by clinical features such as falling toward the site of the lesion, vertigo, diplopia (double vision), Horner syndrome (ipsilateral), loss of nociceptive (pain) and temperature sensation on the opposite side, nystagmus, dysphonia, dysarthria, dysphagia, and decreased gag reflex.

This condition can occur as a result of insult to the lateral medulla, and condition such as infarct of the posterior inferior cerebellar artery is among

the most common cause of Wallenberg syndrome (Sciaccia et al. 2019).

- **Dejerine Syndrome**

The Dejerine syndrome or medial medullary syndrome is characterized by a contralateral weakness and hemi-sensory defects with hypoglossal palsy on the ipsilateral side, caused by an injury to the medial portion of the medulla.

This condition can occur as a result of infarct affecting the hypoglossal nerve nucleus, due to obstruction of the anterior spinal artery or small branches of the proximal or vertebral artery (Sciaccia et al. 2019).

- **Babinski-Nageotte Syndrome**

The Babinski-Nageotte syndrome or hemimedullary syndrome is caused by lateral and medial medullary infarction due to the obstruction of intracranial portion of the vertebral artery.

The clinical features include symptoms of both lateral and medial medulla, cerebellar ataxia (ipsilateral), Horner syndrome, contralateral hemiplegia, hemianesthesia, and sensory deficits of the face (Sciaccia et al. 2019).

- **Hypertrophic Olivary Degeneration**

Hypertrophic olivary degeneration is a rare condition marked by a lesion in the triangle of Guillain and Mollaret (dentato-rubro-olivary pathway), a structure formed by the inferior olivary nucleus, red nucleus, and contralateral dentate nucleus. The hypertrophy affecting the inferior olivary nucleus occurs as a result of transsynaptic degeneration of the central tegmental tract or dentatorubral tract. The clinical features include palatal myoclonus and a rapid spasm of the palate (roof of the mouth) (Sciaccia et al. 2019).

## Conclusion

The medulla oblongata is both anatomically and functionally, a crucial part of the nervous system

located anterior to the spinal cord and forming the lower portion of the brainstem. It contains several ascending and descending tracts that pass through the structure responsible for conveying sensory and motor information between the cortex and the spinal cord. Moreover, several nuclei situated in the medulla give rise to cranial nerves such as the vagus nerve, hypoglossal nerve, and facial nerve that contribute to important functions such as perception of taste, pain, and touch; regulation of the heart rate and blood pressure; and voluntary muscle control. Any damage to the structure may lead to loss of sensory and motor functions, which is also seen in disorders such as Wallenberg syndrome and Babinski-Nageotte syndrome.

## Definition

Pattern of movement observed in Megachiroptera.

Megachiroptera (also known as fruit bats, Old World fruit bats, or megabats) is a suborder of Chiroptera. As of 2018, 197 megachiropteran species have been noted (Almeida et al. 2011). Due to the gracile anatomy of megachiropterans, genetic records have been more reliable than fossils in determining the evolution and lineage of megachiropterans. Based on genetic records, it is suspected that the megachiropterans evolved from Australia or Melanesian Island. The lineage eventually dispersed to mainland Asia, the Mediterranean, and Africa (Almeida et al. 2016). Today, you can find megachiropterans in the subtropical parts of Eurasia, Africa, and Oceania (Almeida et al. 2011). The vast range in megachiropteran migration may be due in part to their adaptive locomotion and anatomy.

Megachiropterans have distinct dog-like faces and have clawed second digits that allow them to climb and walk (Adams and Carter 2017; Granatosky 2018). Megachiropterans vary considerably in size with many species weighing less than 50 gram while some can weigh up to 1.45 kilograms and have a wingspan up to 1.7 meters (Nowak and Walker 1994). Beyond the forelimbs that have been modified into wings, the megachiropterans have large lung capacity (Maina and King 1984), high heart rates (Carpenter 1986), and increased oxygen consumption that permit efficient flight (Maina and King 1984).

Other notable general characteristics of the megachiropterans include sharp eyesight and smell. Unlike microchiropterans, megachiropterans are not known for their echolocating ability (Müller et al. 2007). These bats are typically frugivores or nectarivores (Dumont and O'Neal 2004). Megachiropterans have low reproductive rates (i.e., they produce one offspring at a time) and gestation is generally 4–6 months (Nowak and Walker 1994). Unfortunately, megachiropterans are at potential risk of extinction due to overhunting and habitat destruction.

## Flight Biomechanics

Flight is the primary mode of locomotion in bats, and species can perform complex aerial behaviors, such as hovering or landing head-under-heels (Bergou et al. 2015). The forelimb wing architecture is a major contributor to megachiropteran motion capacity, flight behaviors, and kinematic plasticity. A bat wing is divided into two sections: inner wing and outer wing (Fig. 1). The inner wing, proximal to the first and fifth digits, is formed by propatagium (the leading edge) and the plagiopatagium (membranous structure found between the last digit and the hindlimb). The outer wing has four subdivisions: the dactylopatagium major, dactylopatagium medius, dactylopatagium minus, and dactylopatagium brevis. Proximally to distally, the trailing edge of the wing consists of the plagiopatagium, dactylopatagium major, and dactylopatagium medius (Hedenström and Johansson 2015a, b).

Bat wing skin is thin, soft, anisotropic, and highly deformable. As wing skin is malleable parallel to the trailing edge, it deforms in response to aerodynamic forces (Hedenström and Johansson 2015a). Bat wing skin membrane is stretched by elongated arms and fingers, giving bats the ability to effectively change the overall shape of the wings by flexing and extending their metacarpophalangeal joints and interphalangeal joints (Bahlman et al. 2016). The skin on the wing is composed of living tissue that contains sensors, elastic fibers, and specialized muscles (Hedenström and Johansson 2015b). Tiny hairs on bat wings serve as transmitters of neural signals to provide bats with information on the speed and direction of airflow near the wing. These specialized sensors are most sensitive to the airflow from the trailing edge going toward the direction of the leading edge (Hedenström and Johansson 2015a). Large, well-organized, pre-stretched elastin fibers allow for significant extensibility and efficient packing and unfurling of wings (Cheney et al. 2014; Cheney et al. 2015). Bat wings have long, slender muscles called *m. plagiopatagiales proprii* which are embedded in dermis. These intramembranous muscles are not attached to any bones (Hedenström and Johansson 2015b). The contraction and relaxation

of *m. plagiopatagiales proprii* adjust the curvature of bat wings by tuning the membrane stiffness, thus allowing for support and deformation when aerodynamic load is applied (Cheney et al. 2014). Recent studies demonstrate that aerodynamic performance is improved when artificial wing membranes have electrically controlled compliance (Curet et al. 2014).

Bat wings are framed by bones with varying densities and relative compositions of mineral and protein, thus resulting in varying mechanical properties (Voigt et al. 2017). However, compared to other similar sized mammals, bat wing bones have reduced mineralization, resulting in decreased total weight of the wings (Hedenström and Johansson 2015b). Since the bat skeleton is located close to the wing's leading edge, the wing's center of pressure at which aerodynamic forces act is located posterior to the major bony support (Swartz et al. 1992). As a result, forces applied upwards at the center of pressure produce a torsional force toward the direction of pronation which is then transmitted through the wing membrane and the extended digits (Swartz et al. 1992). Based on analysis of bone deformation patterns during free flight in large bats, researchers proposed that the large cortical diameter and thin walls of the humerus and radius in bats allow

them to reduce weight and withstand large torsional stresses during propulsive downstroke movements (Swartz et al. 1992).

In discussing the wing shape of bats and its relationship with flight biomechanics, the terms wing chord, wingspan, wing area, aspect ratio, and wing loading must be considered. Wing chord, measured parallel to the direction of flight, is the length of the bat wing from the leading edge to the trailing edge. Wingspan is measured from one wingtip to another, while the wing area may be calculated by multiplying the values of wingspan and wing chord. The aspect ratio of a wing is equal to the square of the wingspan divided by the wing area. The wingspan and wing area of megachiropterans increase with body mass, while the aspect ratio rises only slightly with increasing body mass (Norberg and Rayner 1987). Wing loading is equal to the weight of the bat divided by the wing area. Megachiropterans generally have a shorter wingspan, smaller wing area, lower aspect ratio, and higher wing loading in contrast to microbats. Megachiropterans usually fly in straight paths quickly (Norberg and Rayner 1987). Some megachiropterans have been observed to have good maneuverability and slow flight in cluttered environments (Norberg and Rayner 1987). Maneuverability is defined by the space required for a bat to alter its path while flying at a constant speed. Bat wing morphology evolved to be highly specialized to meet the survival needs of the species.

Unlike other flying animals, bats are capable of modulating their wing inertia to produce sophisticated aerodynamic forces (Bergou et al. 2015). This is primarily due to the bat wing's morphological features that allow them to respond efficiently to aerodynamic demands. In evaluating aerodynamic forces produced by flying animals, researchers measure and analyze the structure and motion of wake shed during flight in wind tunnels by using a technique called particle image velocimetry. According to fluid dynamic principles, the wake reflects the magnitude of forces on the wing (Hedenström and Johansson 2015a, b). Studies on wake vortices of bats have demonstrated that the majority of aerodynamic force in bats is produced during the downstroke (Voigt et al. 2017).

As bats flex and extend their digits to different degrees, the wing membrane stiffness changes, affecting the overall three-dimensional shape of the wing. The overall wing shape is defined by camber and angle of attack. In aerodynamics, angle of attack refers to the angle between the wing chord line and the flight direction. Camber, the curvature of bat wings, can be controlled by bats through various ways, such as flexing the fifth digit, deflecting the legs, and elevating or lowering the second digit relative to the main wing surface (Hedenström and Johansson 2015a, b). When bats adjust the wing camber by moving their second digit, the outer wing membrane in front of the third digit functions as a leading-edge flap that modulates the leading-edge vortices (Hedenström and Johansson 2015a, b). In bat wings, the leading edge forms a sharp edge, which facilitates the formation of leading-edge vortices (Hedenström and Johansson 2015a).

Flying animals use leading-edge vortices in close proximity to their wings to help them stay floating in the air. Leading-edge vortices function to improve force generation to maintain vortex lift. Vortex lift increases with greater angle of attack. At slow speeds, bats increase wing force production by controlling leading-edge vortices through adjusting their wing's camber. This increase in force production allows bats to maintain stable flight at slow speeds. To maintain stable leading-edge vortices at the wings, bats need to be able to efficiently control the angle of attack, camber, and wing twist. The leading-edge flap is stabilized by a mechanical locking system (Norberg mechanism) that provides stiffness to the wing's leading edge (Hedenström and Johansson 2015b). Changes in camber and angle of attack determine the lift coefficient, which refers to the capacity of the wing to generate lift. Lift coefficient is defined as  $C_L = 2 L / \rho U^2 S$ , where  $L$  is the lift force,  $\rho$  is air density,  $U$  is local speed about the wing, and  $S$  is the surface area of the wing (Hedenström and Johansson 2015a, b). The speed of the wing relative to the air, the dynamic changes in wing shape, and the lift coefficient determine the magnitude and orientation of aerodynamic forces produced by the

wing (Bahlman et al. 2016; Hedenström and Johansson 2015a).

For flight to occur, bats must produce sufficient lift and thrust by flapping the wings to tilt the lift forward. Thrust is required to reduce the induced drag during flight. Bats adjust the shape and motion of their wings by controlling the strength of the lift, angle of attack, camber, and the speed by which the wing moves through air (Hedenström and Johansson 2015a). When bats change flight speed, they adjust these kinematic parameters to enhance flight stability and performance. The downstroke is responsible for generating both lift and thrust at most speeds, while the function of upstroke changes with forward flight speed (Hedenström and Johansson 2015a). The power required for flight in bats follows a U-shape mechanical power curve (Norberg and Rayner 1987). This curve describes the changes in kinetic energy during the passage of a flying bat. The bottom point of the U-shape mechanical power curve refers to the minimum power speed that should be used by the bat to maximize flight time with a given amount of energy (Norberg and Rayner 1987). An example of a flight behavior representing this point in the U-shape mechanical power curve is nectarivores hovering as they wait their turn to feed. The maximum range speed in the curve represents the energy required to transport the unit weight of the animal through unit distance (Norberg and Rayner 1987). For example, a bat's long-distance flight during mass migration is represented by the maximum range speed in the U-shape mechanical power curve.

When bats fly at slow speeds or hover, such as during foraging in confined spaces for hover-feeding nectarivores, the wake is primarily dominated by downstroke. Three major mechanical constraints on slow flight and hovering performance have been identified: power, wing inertia, and lift generation (Norberg and Rayner 1987). In nectarivore megachiropterans, lift ability during hover-feeding and flight in clutter is enhanced by their large, rounded wingtips, and relatively high wingbeat frequency. During slow speeds and hovering, bats utilize leading-edge vortices to improve lift and an inverted wing during upstroke for additional weight support (Hedenström and Johansson 2015a, b). Since hovering lacks the aerodynamic force from forward speed, flapping

the wings at a higher angle of attack is required. To prevent loss of lift, bats develop leading-edge vortices that enhance the lift and remain stable throughout most of the downstroke (Hedenström and Johansson 2015a, b). During slow flight, there are two simultaneous leading-edge vortices formed at different wing positions and running in different rotation directions. In kinematic upstroke occurring during slow flight, the angle of attack of the outer wing results in leading-edge vortex formation on the underside of the wing concurrently present with another leading-edge vortex formed on the inner wing (Hedenström and Johansson 2015a, b). In contrast, at cruising speeds, where a relatively high drag is experienced, bats often generate two vortex loops at the transition from upstroke to downstroke, reflecting forward thrust and negative weight support (Hedenström and Johansson 2015a, b).

Acceleration and take-off are flight behaviors that do not have a direct relationship with bat wing morphology (Norberg and Rayner 1987). In bats with long and high aspect ratio wings, the energetic cost of acceleration is not high because they are able to generate more force to propel their bodies forward (Norberg and Rayner 1987). On the other hand, acceleration is more energetically expensive among megachiropterans since they generally have a shorter wingspan, smaller wing area, and lower aspect ratio. The presence of high wing loading in megachiropterans gives them the ability for fast but not enduring flight. Take-off from the ground requires movement from rest to overcome inertia. Thus, due to their high wing loading, take-off is also energetically demanding for megachiroptera species (Norberg and Rayner 1987).

### **Terrestrial Walking, Suspensory Walking, and Climbing**

In addition to flight, megachiropterans use quadrupedal gaits during terrestrial walking, suspensory walking, and climbing. Below-branch walking and climbing locomotion are used by the megachiropterans for movement along cave walls, tree trunks and branches, and roosting sites

(Adams and Carter 2017). Compared to terrestrial mammals of similar size, the forearms of bats are long and curved with the radius larger relative to the ulna. Elongated digits support the membranous wing. In the hindlimb, the femur and tibia are long and slim with a fibula either reduced or absent. The hindlimb bones of bats are rotated 90–180° from the typical mammalian pattern. This structure results in the femora extending laterally or caudally and flexor surfaces of knees facing ventrally. As such, terrestrial locomotion is considered awkward and nonlinear when hindlimbs are utilized and energetically expensive. Megachiropterans may attempt to mimic climbing locomotion when placed on the ground. Individuals of *Pteropus pumilus* were seen to utilize a bounding type of locomotion where they pulled themselves along the ground using their forelimbs and thumb claws. Overall, compared to ground dwelling animals of similar size, megachiropterans have poor terrestrial locomotion (Adams and Carter 2017).

In suspensory locomotion, the hindlimbs are used for weight bearing and braking, while the forelimb is the primary propulsive limb with a reduced role in weight bearing. As a limb touches down upon the substrate, the limb applies a propulsive force to the substrate followed by a braking force prior to lift-off. Megachiropterans may shift their body away from their forelimbs as a mechanism to limit the load onto the forelimb. In addition, mediolateral forces help maintain the megachiropteran's "grip" upon a surface when moving below the support (Granatosky 2018). Gait sequences during suspensory walking vary from diagonal-sequence diagonal-couplet all the way to lateral-sequence lateral-couplet (Fig. 2).

Climbing techniques of megachiropterans align with other fully arboreal mammals. Megachiropterans tend to climb in a head-up posture on a vertical surface utilizing an ipsilateral gait with one point of contact to a surface. Megachiropterans are able to cycle their limbs faster when climbing than walking (Adams and Carter 2017). During climbing, the hindlimb is swung through a greater travel arc between fore and aft foot positions relative to the body axis. This allows for foot placement next to or ahead of the

**Megachiroptera Locomotion, Fig. 2** “Hildebrand” plot displaying phase against hindlimb duty factor collected during suspensory quadrupedal walking in *Pteropus vampyrus* ( $n = 43$  strides). Collected from Granatosky (2018)

rostrum, as compared to microchiropterans. In addition, the humerus can extend past the shoulder plane in a swing of  $\geq 180^\circ$ , while microchiropteran rotate their humerus up to the shoulder plane with climbing. Overall, the hindlimbs have been shown to be the generator of climbing thrust with forelimbs utilized for stability (Adams and Carter 2017).

## Bioinspiration

Bats have been used as a source of bioinspired robotics due to their unique wing flexibility and complex wing kinematics. Scientists and engineers have created the Bat Bot, a full self-contained, autonomous flying robot that weighs approximately 93 grams utilizing the morphology of bat wings. An ultrathin silicon membrane is stretched across the skeleton robot that was designed to mimic the bats' membrane. The researchers were able to simplify the 40-joint structure in a way to retain the bats' flight mechanics (Ramezani et al. 2017). Bat-inspired robots have an advantage over current aerial robots, such as the

quadrotors, in that the soft wing of the bat robots offer increased safety when interacting with humans. The bat-like robot flaps its wings at a lower frequency and is created with a flexible material, which allows for collisions with little or no damage. It is hypothesized that constructing bat robots may offer an alternative method of research when studying bat flight biomechanics as opposed to vision-based motion capture systems (Ramezani et al. 2017).

Additionally, bat algorithms, which are meta-heuristic algorithms for global optimization, are being used to develop, something known as, swarm intelligence. Swarm intelligence is the use of simple robotics agents used in groups, or “herds,” to develop a system that can tackle complicated problems and complex situations. Unlike drones, which use a main central intelligence to dictate rules and behaviors of other robots, swarm robotics use multiple simple robots to work together to create a superior system. Members of the swarm communicate with each other and their environment, almost behaving as a flock of birds or a colony of bats, to increase the intelligence of the swarm (Suárez and Iglesias 2017). Possible future applications of swarm robotics include self-driving vehicles used in the military or replacing drone technology with the more comprehensive and less expensive approach of swarm robotics. Among possible swarm robotic models, the bat algorithm has become popular due to its application in solving complex multimodal nonlinear continuous optimization problems with increased variables (Suárez and Iglesias 2017).

## Conclusion

This chapter explores the versatility in megachiropteran locomotion behaviors. The intricate anatomy of their wings has allowed megachiropterans to adapt various forms of flying, hovering, and landing. Megachiropteran flight has also evolved to fit their dietary lifestyle and appropriately balance their energy expenditure in relation to their diet. Due to their ability to acutely modify their wing shape to suit their current

needs, megachiropterans have become of interest to scientific engineering and robotics.

## Megachiroptera Sensory Systems

Andrea Megela Simmons

Department of Cognitive, Linguistic, and Psychological Sciences, Brown University, Providence, RI, USA

## Definition

Auditory, visual, and olfactory capacities of fruit bats.

## Introduction

The order Chiroptera (bats, “hand wing”) comprises over 1000 species, nearly 25% of all mammals. Traditionally, Chiroptera have been classified into two suborders, the Microchiroptera (microbats or echolocating bats) and the Megachiroptera (megabats or fruit bats). This classification has been reconsidered based on new phylogenetic data (Teeling et al. 2005). Bats in the family Pteropodidae (Old World fruit and nectar bats) are discussed in this entry. There are over 180 different species within this family, including the largest known bats, the flying foxes. Some flying foxes can weigh over 1 kg, with wingspans over 1.5 m. The pteropids inhabit Old World tropical forests, as well as grasslands and even desert areas in proximity to fruit or palm agriculture in Africa, Asia, Australia, and the Indian subcontinent. They commonly are encountered in cities in these continents, where they roost in plain sight, typically in trees although sometimes even in buildings or ruins. Fruit bats have doglike faces with elongated muzzles, large frontally facing eyes, and large external ears (Hill and Smith 1984). Most pteropods eat fruit, while others are specialized for feeding on nectar. They play a crucial role in dispersing seeds and pollen within their tropical habitats (Hill and Smith 1984). Fruit bats are also vectors for human diseases; for example, they are the natural hosts for the Nipah and Ebola viruses (World Health Organization 2018, 2019). Understanding the biology and behavior of fruit bats is important for devising control measurements for transmission of these and other zoonotic diseases.

## Audition

Many species of fruit bat are highly vocal, with a rich repertoire of communication sounds. Egyptian fruit bats, *Rousettus aegyptiacus*, are social animals that live in large roosts, typically in caves; roost sizes of up to 10,000 bats have been reported (Prat et al. 2016). To study the social communication of these bats, Prat

et al. (2016) recorded social interactions and concurrent vocalizations of mixed sex groups of 10–12 bats housed in laboratory enclosures for 75 days continuously. The spectral content of 14,863 vocalizations produced by seven adult females fell within the high-frequency range from 5 kHz to 30 kHz. Many of these vocalizations were harmonically structured and consisted of multisyllabic sequences of sounds. By comparing social behaviors with vocalization parameters, the authors were able to classify calls as mating calls, isolation calls, aggressive calls, and distress calls (Prat et al. 2016). Aggressive calls occurred in four different contexts (while mating, while feeding, while competing for perch sites, and while in sleeping clusters). These data indicate that Egyptian fruit bats utilize a complex communication repertoire and highlight the importance of hearing in mediating social interactions within roosts.

Egyptian fruit bats, like some other species of *Rousettus*, echolocate, but by producing short clicks with their tongues rather than by producing tonal or frequency-modulated sounds with their larynx, as do the echolocating microbats (Holland et al. 2004). These clicks contain energy across the frequency bandwidth of 12–70 kHz with peak energy at 20–40 kHz (Holland et al. 2004). Although this click-based echolocation is not as precise as the laryngeal echolocation of the microbats, it is effective in guiding landing on a perch, and it allows the fruit bats to detect the presence of medium-sized objects even in total darkness (Yovel et al. 2011). Some other megabats (the cave nectar bat, *Eonycteris spelaea*; the lesser short-nosed fruit bat, *Cynopterus brachyotis*; and the long-tongued fruit bat, *Macroglossus sobrinus*) produce clicks using their wings rather than their tongues. These species can detect large objects in the dark with these clicks (Boonman et al. 2014).

Psychophysical measurements of the hearing sensitivity of Egyptian fruit bats (Koay et al. 1998) show that their range of hearing extends from about 2 to 64 kHz (measured at a criterion level of 60 dB SPL), overlapping the spectral content of both communication sounds and echolocation clicks. The audiogram shows a

region of best sensitivity between 8 and 25 kHz, at a low threshold of 4 dB SPL. This low threshold is comparable to that of echolocating bats within their best region of sensitivity (Tuninetti and Simmons 2019).

Fruit bats have large external ears (which are often scaled with the length of the muzzle), but their external ears are smooth, without the ridges and folds characteristic of the ears of echolocating bats (Hill and Smith 1984). In addition, their ears lack a tragus, a structure important for vertical sound localization in insectivorous echolocating bats (Lawrence and Simmons 1982). The general structure of the inner ear in adult fruit bats is similar to that of non-echolocating mammals and without the specializations typically seen in the inner ears of echolocating bats (Tuninetti and Simmons 2019). The cochlea is smaller, and the basilar membrane is shorter than those of echolocating bats, even after accounting for the larger body size of the fruit bats and even when the click-based echolocators are included in the comparisons (Habersetzer and Storch 1992; Davies et al. 2013). In addition, the volume of the auditory midbrain (inferior colliculus) in the fruit bat brain is smaller than that in the insectivorous bat brain, again after controlling for body size (in 63 species, Hutcheon et al. 2002; in 7 species, Liu et al. 2015).

## Vision

Most fruit bats leave their roosts shortly before dusk in order to forage, although some species are also active at higher light levels. As expected from these daily activity patterns, their eyes are specialized for scotopic (low light) vision. The greater Indian flying fox, *Pteropus giganteus*, has large eyes with large spherical lenses and a wide binocular field (Neuweiler 2000). Even when corrected for body size, eyes of fruit bats are larger than those of insectivorous bats (Bojarski and Bernard 1988; Neuweiler 2000). The eyes of some species of fruit bat [the greater Indian flying fox; Madagascar rousette (*Rousettus madagascariensis*); Madagascar straw-colored fruit bat (*Eidolon dupreanum*);

and Gambian epauletted fruit bat (*Epomophorus gambianus*)] also include a tapetum lucidum (“shining layer”). The tapetum is the reason for the “eyeshine” observed in the eyes of nocturnal animals (Ollivier et al. 2004). This structure operates to reflect light not captured by the retina back into the photoreceptor layer, and so it works to increase sensitivity of vision, but at the cost of resolution.

Structural studies of the retina of Egyptian fruit bats reveal other adaptations for vision in low light. In these bats, the retina is thick and folded in such a way so as to increase its surface area, and thus the number and density of photoreceptors can be packed into it (Bojarski and Bernard 1988). Large numbers of photoreceptors can transduce more light and thus increase sensitivity. There is no fovea and thus no region of improved spatial resolution (Müller et al. 2007). The vascular layer (choroid) of the eye contains protuberances, called papillae, that extend into the retina, making “its surface look like a volcanic landscape” (Neuweiler 2000, p. 215). This organization appears to be unique among mammals. The function of these papillae is still debated. One possibility is that they improve the oxygen supply to the retina, which is not itself vascularized (Müller et al. 2007).

The fruit bat retina was until recently believed to contain only rod photoreceptors, which are specialized for detecting dim light (Neuweiler 2000). Müller et al. (2007), using immunocytochemistry for opsin antibodies, uncovered the presence of cone photoreceptors in the retinas of six different species [the Madagascar rousette; Madagascar straw-colored fruit bat; Gambian epauletted fruit bat; Madagascar flying fox (*Pteropus rufus*); greater Mascarene flying fox (*Pteropus niger*); and Rodrigues flying fox (*Pteropus rodricensis*)]. Retinas of all of these species were indeed dominated by rods, but between 0.25 and 0.6% of the total photoreceptors were cones. Two types of cone photoreceptors (“blue” and “green”) were identified in the three species of *Pteropus*, while only one type (“green”) was present in *Rousettus*, *Eidolon*, and *Epomophorus*. Melin et al. (2014) identified two cone types in the retina of Samoan flying foxes

(*Pteropus samoensis*), confirming that some fruit bats have the retinal substrates for dichromatic color vision. The presence of only one cone type in *Rousettus*, *Eidolon*, and *Epomophorus*, on the other hand, suggests that these species are color-blind.

There is little information on the organization or function of central visual pathways in fruit bats. Studies mapping out neural responses to visual stimulation determined that almost one-half of the entire neocortex of the grey-headed flying fox (*Pteropus poliocephalus*) is related to visual processing, a much greater proportion than in insectivorous bats and even larger than expected for mammals of similar body weight (Rosa 1999). Another study based on manganese-enhanced multiple resonance imaging showed that the visual midbrain (superior colliculus) is larger in fruit bats than in insectivorous bats, which is opposite to the pattern seen when comparing the sizes of the auditory midbrain in these animals (Liu et al. 2015).

Field observations suggest that visual acuity and sensitivity differ between fruit bat species based on their activity patterns and roosting sites. *Pteropus* often forage during the day and live in tree roosts that can be exposed to sunlight. They also use postural displays for conspecific communication (Kunz 1982). Thus, these bats should have better vision at higher light levels than *Rousettus*, which roost in caves. Psychophysical data quantifying these possible species differences in visual sensitivity are few. When tested at low light levels, the visual acuity of the greater Indian flying fox in some visual tasks seems to exceed that of humans. These bats were able to discriminate black from white stripes at down to stripe widths of 9 mm, compared to the 15 mm limit of human performance (Neuweiler 2000).

## Olfaction

Fruit bats forage on ripe fruits, typically at dusk but sometimes also during daylight hours. Olfactory acuity of some species has been tested

in several laboratory experiments. Luft et al. (2003) questioned whether little golden-mantled flying foxes (*Pteropus pumilus*) and greater musky fruit bats (*Ptenochirus jagori*) could discriminate between an empty dish and one containing fruits (banana, mango, or fruits from local wild plants and shrubs) by odor alone. Even though visual cues were eliminated by covering the dishes with gauze in these two-choice tests, both species chose the fruit dish consistently (choice ratios of 7–10). In addition, the bats were able to discriminate ripe from unripe fruits (choice ratios of 9–10). In these experiments, bats were tested in laboratory cages where the distances to the dishes were small (0.5–1.5 m), so the distance from which bats may be able to detect the odors of ripe fruit in natural foraging could not be determined. Hodgkison et al. (2007) examined the role of odor cues in foraging in four different species [the short-nosed fruit bat (*Cynopterus brachyotis*); spotted-wing fruit bat (*Balionycteris maculata*); black-capped fruit bat (*Chironax melanocephalus*); and Horsfield's fruit bat (*Cynopterus horsfieldii*)]. Bats were housed in a large flight cage in the laboratory and foraged in the dark for figs. Foraging behavior, quantified by landing and then feeding, was strong (95–100% correct performance) to ripe figs, but significantly less to unripe figs (5%). These data suggest that the odors of the figs were more important in foraging than any visual cues that may have been available.

Fruit bats may also use odors for conspecific communication. Indian short-nosed fruit bats (*Cynopterus sphinx*) form tight clusters in their roosting spots and groom one another. Bats in these grooming clusters were observed to be wet with saliva and with secretions from sebaceous glands and the anogenital area (Neuweiler 2000). Laboratory assays showed that these secretions contain several volatile organic compounds, suggesting that they may function as pheromones. But the presence of pheromonal communication has not been directly tested in this species.

Consistent with the reliance on odors for foraging and their possible use in chemical communication, fruit bats have large nasal cavities,

with the olfactory epithelium considerably thicker than that of insectivorous bats (Neuweiler 2000). Olfactory bulbs of fruit bats are larger than those of insectivorous bats, even after correcting for body size; comparatively, the differences in sizes of the olfactory bulbs exceed those of the auditory midbrain (Hutcheon et al. 2002). Nothing is known, however, about receptor sensitivity, either for olfactory or for taste receptors.

## Conclusion

Fruit bats rely on both visual and olfactory senses to guide their foraging behaviors, with olfaction seemingly the predominant sense. Odors allow bats to discriminate ripe from unripe fruits, a task that would be difficult using visual cues only. And although fruit bats forage on many different kinds of fruits and flowers, there is no quantitative data on their taste sensitivity. Fruit bat eyes are specialized for seeing in low light levels, with adaptations for sensitivity but at the expense of resolution. Although some species seem to have the capacity for color vision, it is not known if they can behaviorally discriminate objects based on color cues. Because echolocation is limited to only a few species, and the acuity of this click-based echolocation is poorer than that of the laryngeal echolocators, it is likely that fruit bats rely on vision rather than hearing to navigate through their environments and to find food sources over large distances. The large external ears and the large vocal repertoire of several species of fruit bats suggest that hearing mediates social communication. It is also possible that chemical cues play a role in mediating social behaviors, particularly in roosts, but this has not been studied systematically. Most of our information on the sensory capacities of the more than 180 species of fruit bats comes from field observations, and there is very little quantitative psychophysical data available on their sensory acuity.

Fruit bats play crucial roles in tropical ecosystems by their activities in dispersing seeds and pollinating plants. They are also vectors for

many pathogens that can affect humans and domestic animals. Understanding fruit bat behavior, including their sensory capacities, will facilitate informed decisions about regulating human-bat interactions to decrease disease transmission and devising conservation measures critical to maintaining their role as pollinators.

## Melanin

Karthikeyan Pethusamy<sup>1</sup>, Ruby Dhar<sup>2</sup> and Pinky Garg<sup>3</sup>

<sup>1</sup>Department of Biochemistry, All India Institute of Medical Sciences (AIIMS), New Delhi, India

<sup>2</sup>Biochemistry, All India Institute of Medical Sciences, New Delhi, India

<sup>3</sup>Biochemistry, North Delhi Municipal Corporation Medical College, New Delhi, India

## Introduction

Melanin refers to a group of natural pigments found in the animal kingdom and fungi. Melanin is responsible for the color of skin, hair, and iris.

## Types and Distribution of Melanin

There are three types of melanin namely eumelanin, pheomelanin, and neuromelanin. Eumelanin is the most common type. Pheomelanin is a cysteine derivative responsible for the red hair. As the name suggests, neuromelanin is found in the brain and produced by dopaminergic and noradrenergic neurons located in the substantia nigra and locus coeruleus.

## Melanogenesis

Melanogenesis is the process of synthesis of melanin. It takes place in the melanosomes found inside melanocytes. Melanosomes are small, membrane-bound, specialized organelles related to lysosomes. Melanosomes are transported from melanocytes to the adjacent keratinocytes through the finger-like (dendritic) projections of melanocytes. Melanin protects the skin from the DNA-damaging effect of UV light.

Melanocytes are derived from melanoblasts which themselves are derived from neural crest cells. Melanogenesis takes place in the skin, hair, eyes, ears, and leptomeninges. The UV radiation

is the primary stimulus for melanogenesis. This is the basis of tanning of skin (increased melanin synthesis) after prolonged sun exposure. People with less melanin are more susceptible to sunburn. Fitzpatrick scale is a numerical classification system based on the susceptibility for tanning and sunburns (Altieri et al. 2017). People with Fitzpatrick type I skin contains less melanin so that they always get sunburns and never get tanned whereas people with Fitzpatrick type VI skin contains more melanin so that they never get sunburns.

In animals, melanocytes are located at the basal layer of the epidermis of the skin. Eumelanin and pheomelanin are produced from the oxidation and polymerisation of the hydroxyl group-containing amino acid tyrosine. Tyrosinase is the rate-limiting enzyme of melanogenesis. The enzyme first hydroxylates tyrosine to dihydroxyphenylalanine (DOPA) and then oxidizes it to dopaquinone. Further reactions yield various types of melanin.

## Melanin and the Iris Color

The amount of melanin does not only determine the color of the skin, but also the iris. The high amount of melanin produces black or dark brown iris whereas the low amount of melanin leads to blue colored iris (Sturm and Larsson 2009). Melanin in the iris serves to protect the retina from the damaging effect of light.

## Albinism

Overproduction, as well as underproduction of melanin, can happen. Albinism is a group of congenital hypopigmentation disorders inherited in recessive mode. Albinism produces white fur and red eyes in mammals and white plumage, red eyes, and white claws in birds. Many zoos keep albino animals for the purpose of visitor attraction. Albino rats have been used as laboratory animals for the past 150 years, and in fact they were the first animals to be domesticated for

the purpose of scientific research (Kuramoto et al. 2012).

In humans, when albinism is limited to skin and hair, it is known as cutaneous albinism. People with cutaneous albinism have melanin in their eyes. Oculocutaneous albinism (OCA) refers to the absence of melanin in skin, eyes, and hair. People with OCA suffer from skin cancer, nystagmus (involuntary eye movement), photophobia (aversion to light), and poor eyesight. Skin cancer is due to loss of protective effect of melanin against DNA-damaging UV radiation.

## Fungal Melanin

Melanin is not only produced by animals but also by fungi. Fungal melanin is different from animal melanin. 1,8-dihydroxynaphthalene (DHN) is the major melanin of fungi. It is synthesized from acetyl-CoA through the polyketide pathway. Some pathogenic fungi like *Cryptococcus neoformans*, *Candida albicans*, and *Paracoccidioides brasiliensis* can produce eumelanin also. Fungal melanin is involved in the virulence (disease-causing ability) of the pathogenic fungi (Nosanchuk and Casadevall 2006).

## Cephalopod Ink

In the animal kingdom, melanin is not just a body pigment. Animals have evolved to use melanin for various other purposes. When threatened, many cephalopods release dark-colored ink. The major constituent of the cephalopod ink is melanin. The ink is secreted by the ink sacs located between the gills. The release of ink is accompanied by the water jet and creates a smoke screen and allows the escape of cephalopod.

## Definition

The set of three laws, proposed by Gregor J. Mendel in the mid-1860s, to explain the biological inheritance or heredity is known as Mendel's laws. These laws are the law of segregation, law of independent assortment, and law of dominance, and they form the core of classical genetics to date.

## Introduction

Gregor Johann Mendel (1822–1884) was a friar-cum-science teacher in Brno (Austria-Hungary), and known as the father of genetics due to his groundbreaking genetics experiments on sweet pea plants. Though he performed and published his scientific work in the 1860s, significance of his work was not widely recognized until 1900. His scientific results describe the transmission of hereditary information from parent generation to

progeny generation. These results helped him to frame three laws of biological inheritance, which led to the foundation of classical genetics. Mendel's contribution is significant in genetics as he framed these laws during a time when even words like “chromosomes” or “genes” were not discovered (Hartl and Ruvolo 2011).

Mendel crossed white flower and purple flower pea plants (parents or P generation) and found out that the progenies (F1 generation) were purple-flowered plants rather than a blend. Interestingly, when he self-fertilized these progenies, he got both purple flower and white flower plants (F2 generation) in the ratio of 3:1. The results of this cross are summarized in Fig. 1.

### First Law: Law of Dominance

When individuals with one or more sets of contrasting characters (now known as phenotypes) are crossed, then the characters that appear in F1 generation are called dominant characters, and the characters that remain hidden are called recessive characters. The above example, where P generation plants were crossed together and only purple-colored flower F1 generations were

obtained, shows that the dominant purple flower allele (B) will hide the phenotypic effects of the recessive white flower allele (b). This is known as the law of dominance (Hartwell et al. 2017). White phenotypes will appear only in the absence of dominant purple flower alleles. The uppercase letters are used to denote dominant alleles, whereas the lowercase letters are used to denote recessive alleles. Mendel used the term “factors” instead of alleles during that time.

### Second Law: Law of segregation

This law is also referred to as *law of purity of gametes*. During the formation of male and female gametes (generally sperm and ova in animals or pollen grains and ovule in plants), factors (alleles) responsible for a particular character separate and are passed into different gametes. This process implies that the gametes are either pure for dominant alleles or for recessive. These gametes can unite randomly in different possible combinations during fertilization and produce the genotype for the traits of the progenies (Pierce 2017). In a zygote, the two members of an allele pair remain together without being contaminated. This is known as law of segregation.

In Fig. 1 above, both pollen and pistil form male and female gametes, respectively, with either B or b allele. These male and female gametes combine randomly during fertilization to produce F1 generation of purple flower and white flower plants in the ratio of 3:1.

### Third Law: Law of Independent Assortment

This law is also known as *inheritance law* and is defined as alleles of different genes which distribute independently of one another during gamete formation (Watson et al. 2013).

As shown in Fig. 1, mixing a single trait (monohybrid cross) in Mendel's experiment constantly resulted in a 3:1 ratio between dominant and recessive phenotypes. However, when he performed experiments on two traits (dihybrid

|             |   |                                                                                           |                                                                                           |

cross), he obtained F<sub>2</sub> generation in the ratio of 9:3:3:1 (Fig. 2). These results led Mendel to conclude that different traits (e.g., seed shape and color) are inherited independently of one another and there is no relation between two traits.

## Conclusion

Historically, biologists in the nineteenth century believed in the apparent blending of inherited traits in the overall appearance of the progeny, which proved to be a major roadblock for the understanding and acceptance of Mendel's work. It was only in the year 1900 (16 years after Mendel first published his studies) where three European scientists, i.e., Hugo de Vries, Carl Correns, and Erich von Tschermak, rediscovered Mendel's work by performing similar experiments independently (Snustad

and Simmons 2015). William Bateson was a huge promoter of Mendel's work later in Europe and also coined the terms genetics, gene, and allele to describe the basic constituents of Mendelian genetics.

With the advancement in the field of genetics, scientists observed few deviations from Mendel's laws of inheritance. These include incomplete dominance, codominance, and lethal genes.

## Definition

A set of breeding experiments and carefully augmented observations, performed on sweet pea (*Pisum sativum*) to understand the pattern of inheritable characters or traits, which led to three basic principles that are the pillars of classical genetics.

## Introduction

Gregor Johann Mendel (1822–1884) was an Austrian (now Czech Republic) priest-cum-scientist who is known for his extraordinary work on sweet peas and is essentially considered as the father of

modern genetics. In 1853, upon completion of his studies from the University of Vienna, he joined a monastery in Brno (called *Brünn* in German) as a science teacher and began his groundbreaking work on sweet peas to understand the basic mechanism of heredity. To understand the mechanism, he chose sweet pea plants considering few essential and critical points. Peas are easy to cultivate, easily available, have shorter generation time, produce large number of progeny in terms of seeds, and possess distinct and easily observable external characters and, more importantly, fertilization between two plants can be easily controlled. Peas possess both male reproductive structure (stamens) and female reproductive structure (pistils) and self-fertilize normally; i.e., anthers located at the end of the stamen produce pollen (germinates to form male gametophyte) that falls on the pistils (containing female gametophyte) of the same flower and undergo fertilization. Thus, fertilization could be selectively controlled through removal of the stamens (emasculation) from a developing flower before it starts producing mature pollen and transferring the pollen from one pea plant to pistils of emasculated desired flower with a small paint brush. Mendel started with 34 strains of pea plant having different traits and allowed them to self-fertilize for a number of generations to get pure-breeding or true-breeding strain – which shows the same traits generation after generation (Russel 2010). Based on the strains, Mendel selected seven traits that were clearly distinguishable from each other and went for cross-fertilization that are as follows:

| Traits                 | Phenotypic features for crosses                                                 |
|------------------------|---------------------------------------------------------------------------------|
| <b>Coat color</b>      | <b>Seed coat:</b> Grey versus white<br><b>Flower color:</b> Purple versus white |
| <b>Seed color</b>      | Yellow versus green                                                             |
| <b>Seed shape</b>      | Smooth versus wrinkle                                                           |
| <b>Pod color</b>       | Green versus yellow                                                             |
| <b>Pod shape</b>       | Inflated versus pinched                                                         |
| <b>Stem height</b>     | Tall versus short                                                               |
| <b>Flower position</b> | Axial versus terminal                                                           |

Mendel extensively used breeding experiments or genetic crosses to get ideas about the inheritance pattern. Certain terminologies are very

much essential to start with breeding experiments. The Parental generation, with which the experiment or breeding started, is P generation. The progeny of the p generation are referred as F<sub>1</sub> or *first filial generation*. The subsequent progeny produced by the interbreeding of F<sub>1</sub> generations are called *second filial generation* or F<sub>2</sub> and so on. The filial word originally came from Latin word *filia* (daughter) and *filius* (son).

Monohybrid Crosses

Mendel started his experiment considering a single trait at a time or Monohybrid crosses, i.e., crossing between those pure lines that differ by a single character. While doing so, he simultaneously examined reciprocal crosses to check whether sex has an influence on inheritance or not. Mendel carried out 60 such experiments but, in all his reciprocal crosses, he never encountered any differences in F<sub>1</sub> generation (as all the genes/traits were autosomal fortunately). Not only that, he also observed that F<sub>1</sub> progeny of all the pure breed monohybrid crosses showed only one of the parental phenotype.

In one such experiment, he crossed pure breed of *round seeds* with pure breed of *wrinkled seed* plants and found that all the progeny showed round seed phenotype F<sub>1</sub> generation; even in reciprocal crosses. But when he allowed F<sub>1</sub> generation for self-fertilization, both the parental trait (i.e., round and wrinkled seeds) was recovered in F<sub>2</sub> generation. So he counted the total 7324 seeds and found 5474 seeds were rounded and the rest of the 1850 seeds were wrinkled which typically resemblances 3:1 ratio (~ 2.96:1); that is, three-fourth of the seeds were round and one-fourth of the seeds were wrinkled phenotypically. He did the same experiment with all seven pure breeds and obtained the same ratio of distribution in F<sub>2</sub> generation (Griffiths et al. 2015).

| Parental phenotype              | F <sub>1</sub> phenotype | F <sub>2</sub> phenotype     | F <sub>2</sub> ratio |
|---------------------------------|--------------------------|------------------------------|----------------------|
| Round seeds<br>X wrinkled seeds | All round seeds          | 5474 round;<br>1850 wrinkled | 2.96:1               |

(continued)

| Parental phenotype                | F <sub>1</sub> phenotype | F <sub>2</sub> phenotype     | F <sub>2</sub> ratio |
|-----------------------------------|--------------------------|------------------------------|----------------------|
| Yellow seeds<br>X green seeds     | All yellow seeds         | 6022 yellow;<br>2001 green   | 3.01:1               |
| Purple petals<br>X white petals   | All purple petals        | 705 purple;<br>224 white     | 3.15:1               |
| Green pods<br>X yellow pods       | All green pods           | 428 green;<br>152 yellow     | 2.82:1               |
| Inflated pods<br>X pinched pods   | All inflated pods        | 882 inflated;<br>299 pinched | 2.95:1               |
| Axial flower<br>X terminal flower | All axial flower         | 651 axial;<br>207 terminal   | 3.14:1               |
| Long stems<br>X short stems       | All long stems           | 787 long;<br>277 short       | 2.84:1               |

Outcome of Monohybrid Crosses

In such crosses, Mendel clearly observed that one of the parental traits disappears in F<sub>1</sub> but reappears in F<sub>2</sub> generation – also in 3:1 ratio consistently. Reappearance of both of the parental characters in F<sub>2</sub> could only be explained if F<sub>1</sub> possess both the factors controlling round and wrinkled seed character – inherited from P generation. So, Mendel concluded that each trait is controlled by the *two inheritable factors* and such factors are now called alleles.

Mendel, by convention, designated traits with single letters with upper and lower case. So, he used *R* for round seeds and *r* for wrinkled seeds. As the parental lines were true breeding, they possessed both the identical alleles of the same character (*homozygous condition*); *RR* for round seeded and *rr* for wrinkled seed P-generation (now called *genotype*).

The second conclusion drawn by Mendel on such monohybrid crosses was that during gamete formation, two alleles get segregated and one gamete receives only one allele. One such gamete from the male and another one from the female fuse to form the zygote, and thus, it contains both the contrasting alleles for the same character or trait (*heterozygous condition*). Thus, all the progeny of F<sub>1</sub> generation received both *R* and *r* alleles. Surprisingly, only *R* alleles expressed in the form of round seeds though *r* alleles were also there

with  $R$  allele simultaneously – but  $r$  failed to express. Mendel considered such characters as *dominant* that expressed in  $F_1$  generation in heterozygous condition and the counterpart as *recessive*. Essentially, the dominant allele suppresses or masks the effect of recessive allele in heterozygous condition, which helped Mendel to draw another important concept of heredity – *i.e.*, *dominance*. It was the third important concept concluded from monohybrid crosses by Mendel.

Mendel drew a fourth conclusion from here that alleles of the same trait get equally separated during gamete formation and randomly pair with allelic partners during zygote formation – coming from another mating partner. So all the progeny of  $F_1$  generation received  $R$  from round seeded parent ( $RR$ ) and  $r$  from wrinkled seeded parent ( $rr$ ) and they were heterozygous ( $Rr$ ). As  $R$  was found to be dominant over  $r$ , all the  $F_1$  progeny became round seeded. But during self-fertilization among  $F_1$  progeny, all of them produced two types of gamete,  $R$  and  $r$ . Hence, in  $F_2$ , genotypically four different types of progeny –  $RR$ ,  $Rr$ ,  $rR$ , and  $rr$  –

were produced in equal proportion because of random pairing among gametes. As  $R$  is dominant over  $r$ ,  $RR$ ,  $Rr$ , and  $rR$  progeny were round seeded and  $rr$  was the only one with wrinkled seeded phenotype ( $Rr$  and  $rR$  are same both genotypically and phenotypically – by convention both of them represented as  $Rr$  considering dominance of  $R$  over  $r$ ). Moreover, distribution of round to wrinkled seed progeny in 3:1 ration in  $F_2$  reconfirms third conclusion and random pairing of alleles occur during gamete formation.

Based on such conclusions, Mendel formulated the principle of segregation and concept of dominance. Principle of segregation is referred as *Mendel's first law*, and it states that each diploid organism possesses two alleles for a particular character or trait. Such alleles get separated during gamete formation and segregate in equal proportion and each gamete receives only one allele for a particular trait. According to the concept of dominance, when two different alleles for a particular trait present together, only one allele expresses by masking the expression of other allelic partner.

**Mendelian Crosses, Fig. 1** Monohybrid cross: Parental traits do not blend with each other. Dominant traits are expressed in  $F_1$  generation, but both the parental phenotypes are found in  $F_2$  in 3:1 ration

The allele that masks or suppresses the expression of other allele is referred to as dominant and the counterpart is called the recessive allele (Snustad and Simmons 2015).

Mendel further confirmed his results by extending up to  $F_6$  generations by allowing self-fertilization of progeny and observing similar phenotypic ratio of round and wrinkled seeded plants in consistency, as found in  $F_3$  (Figs. 1 and 2).

### Di-hybrid Crosses

Mendel extended his work into more complex forms to understand the hereditary dynamics of two traits when they are present together in a single parent. He crossed one homozygous parent having round and yellow seed ( $RRYY$ ) with homozygous plants showing wrinkled and green seed ( $rryy$ ). In  $F_1$  generation, he found all the progenies showed round and yellow seed phenotype ( $RrYy$ ), similar to

the outcome of monohybrid crosses. Then he allowed self-fertilization of  $F_1$  progeny and found four different phenotypes in  $F_2$  generation: round and yellow seeds ( $RRYY$ ) – 315, wrinkled and yellow seeds ( $rrYy$ ) – 101, round and green seeds ( $Rryy$ ) – 108, wrinkled and green seeds ( $rryy$ ) – 32. When Mendel calculated the results, he obtained 9:3:3:1 ratio of phenotypic distribution. He observed that among total progeny  $\frac{9}{16}$  of them round and yellow seeded,  $\frac{3}{16}$  of them were having wrinkled and yellow seeded,  $\frac{3}{16}$  were round and green seeded, and rest  $\frac{1}{16}$  of them were wrinkled and green seeded. He observed similar  $F_2$  phenotypic ratio in all other di-hybrid crosses as well.

Such a result perfectly satisfies the principle of segregation and concept of dominance along with another fundamental aspect of heredity – the *principle of independent assortment*. This is referred to as the *third law of Mendel* and it states that

**Mendelian Crosses, Fig. 2** Monohybrid crosses satisfying principle of segregation and concept of dominance

M

**Mendelian Crosses, Fig. 3** Dihybrid cross: Alleles responsible for seed color and seed shape assorted independently during gamete formation and producing 9:3:3:1 phenotypic ratio in F<sub>2</sub> generation

during gamete formation all the alleles from different traits assorted independently of one another (Pierce 2012).

The first law of Mendel essentially refers to the separation of alleles of the same trait, whereas the principle of independent assortment reflects the separation of alleles of different traits independently from one another. Indeed, the first law of Mendel is an extension of the later one.

Besides that, it was significantly found that alleles of different traits are separated independently and finally combine with all possible combinations during zygote formation. Thereby, during gamete production, P generation produced two types of gamete  $RY$  and  $ry$ . They fused to form  $RrYy$  progeny in  $F_1$  generation. When  $F_1$  progeny were allowed for self-fertilization, they produced four different types of gametes –  $RY$ ,  $Ry$ ,  $rY$ , and  $ry$  – and formed zygotes with all possible combinations equally. As  $R$  is dominant over  $r$  and  $Y$  over  $y$ , all  $F_1$  progeny were round and yellow seeded. But in  $F_2$ , as alleles were independently assorted during gamete formation, they combined to produce two new phenotypes showing mixed parental traits. But because of independent assortment, both the parental traits were recovered along with heterozygous parental phenotypes. Mendel further confirmed heterozygous and true breeding parental phenotypes via self-fertilization  $F_2$  progeny for successive generations. External features of traits are now called *phenotype*, and genetic makeup or genetic constituent of an organism is called *genotype*. Essentially, because of dominance and independent assortment, 9:3:3:1 phenotypic ration was obtained in  $F_2$  generation (Hartl and Ruvolo 2011, Fig. 3).

## Discussion

Understanding of inheritable traits or characters provides an idea about the dynamics and flow of the characters over generations. Mendel provided experimental support and mathematical explanation about the dynamics of such inheritable traits for the first time way back in nineteenth century when almost nothing was known about that. Later on, such inheritable traits were defined as genes (named by W. Johannsen) that are located in a

specific location on the chromosome (*loci*) and regulate traits via their expression. But till 1900, the significance and impact of Mendel's work was not recognized until three different scientists – Hugo de Vries, Eric von Tschermak, and Carl Correns – derived similar results independently while working with plants. Not only that, understanding of meiosis and gametogenesis further clarified Mendel's principles. Although Mendel worked on plants, such principles are applicable on all chromosomal inheritance, which made him the father of genetics. But detailed understanding of complex molecular genetics hint that Mendel was a bit lucky to obtain such consistent results as pea is a diploid organism and all the characters chosen by Mendel were located on different chromosomes, including the fact that he did not encounter any extra chromosomal inheritance. Nevertheless, his work revealed a new dimension of understanding genetics and eventually he laid the foundation for the most remarkable principles of inheritance.

## Messenger RNA

Alaknanda Mishra  
National Institute of Immunology,  
New Delhi, India

### Synonyms

[mRNA](#); [Template RNA](#); [Informational RNA](#)

### Definition

The form of RNA which carries information from nuclear DNA to the ribosomal sites of protein synthesis in the cell.

### Introduction

Messenger RNA (mRNA) is a single-stranded nucleotide sequence that carries genetic information from the master molecule DNA in the form of codons (series of three bases which specifies a particular amino acid). It comprises only about 5% of the total RNA in the cell and is the most heterogeneous RNA which varies in the coding region. It was discovered in the year 1960 at the California Institute of Technology by Sydney Brenner, François Jacob, and Matthew Meselson (Ullmann [2011](#)).

### Messenger RNA Structure

The mRNA molecule also known as the “transcript” is generally 300–50,000 nucleotides in length and varies in prokaryotes and eukaryotes. mRNA forms in the nucleus of eukaryotic cells; however, owing to the absence of nucleus in prokaryotes, the mRNA is made directly off of the DNA in the cell’s cytoplasm. The backbone of mRNA contains five-carbon sugar ribose which includes nucleotide bases uracil instead of thymine in the prokaryotes (Kozak [1983](#); Shabalina et al. [2006](#)). Structurally, it consists of Cap,

**Messenger RNA, Fig. 1** Representative image of an mRNA codon

noncoding region, an initiation codon, and coding region (Fig. 1).

### 5' Cap

A 5' cap is also called as RNA cap or RNA 7-methylguanosine cap. A modified guanine nucleotide which is added to 5' end of a eukaryotic messenger RNA immediately after transcription starts forms the RNA cap. The terminal 7-methylguanosine residue which constitutes RNA cap is linked through a 5'-5'-triphosphate bond to the first transcribed nucleotide. This modification facilitates the recognition and attachment of mRNA to the ribosome, as well as protection from degradation by 5' exonucleases. Besides, it is also crucial for other functions such as splicing and transport (Kozak 1983).

### Coding Regions

Coding regions consist of codons, which are decoded and translated by the ribosomes into one (mostly eukaryotes) or many (mostly prokaryotes) proteins. Coding regions have a start codon as the beginning sequence and end with a stop codon. Generally, AUG triplet is the start codon and UAA, UAG, or UGA are the stop codons. The coding regions are made stable by the internal base pairs which prevents their degradation (Katz and Burge 2003; Shabalina et al. 2006). Codons not only act as protein-coding regions but may also serve as regulatory sequences in the pre-mRNA as exonic splicing enhancers or exonic splicing silencers.

### Untranslated Regions (5' UTR and 3' UTR)

Untranslated regions (UTRs) are sections of the mRNA before the start codon and after the stop codon that are not translated and are termed as 5' UTR and 3' UTR, respectively. Since these

regions are transcribed with the coding region, they form a part of the exons and present in the mature mRNA. Various functions in gene expression, mRNA stability, mRNA localization, and translational efficiency have been attributed to untranslated regions (Kozak 1983; Shaw and Kamen 1986). The capability of UTR to perform such functions is sequence dependent and can vary. UTRs have variable affinity toward ribonucleases and ancillary proteins that promote or inhibit RNA degradation. Proteins or microRNAs that bind to either the 3' or 5' UTR modulate the translational efficiency by affecting the ribosome's ability to bind to the mRNA.

3' UTR also functions to determine the cytoplasmic localization of the proteins. UTRs also form characteristic secondary structures when transcribed into RNA which are responsible for mRNA regulation and also form targets for protein binding (e.g., SECIS element). Another class of mRNA elements, the riboswitches, modify the levels of transcription or translation by directly binding small molecules and changing their fold expression, thus regulating themselves (Copeland et al. 2001; Ren et al. 2017; Shabalina et al. 2006).

### Poly(A) Tail

The 3' poly(A) tail is a long sequence of several adenine nucleotides located at the 3' end of the pre-mRNA which facilitates the export from the nucleus, promotes translation, and hinders mRNA degradation (Shabalina et al. 2006).

### Monocistronic Versus Polycistronic mRNA

An mRNA molecule is monocistronic when it translates into a single protein which mostly

occurs in eukaryotes (Kozak 1983). Polycistronic mRNA carries information of several gene proteins and is translated into several proteins. These multiple proteins share related functions and are regulated together in an operon which mostly occurs in prokaryotes.

## Processing and Function

The life of mRNA molecule begins with transcription and ultimately ends in degradation. During its existence, the mRNA molecule can possibly undergo processing, edited and transported before being translated. This process is more common in eukaryotes than prokaryotes.

## Transcription

The process of transcription is similar in both prokaryotes and eukaryotes where the enzyme RNA polymerase makes a copy of a gene from the DNA to mRNA as required. However, the eukaryotic RNA polymerases are associated with mRNA processing enzymes while transcription is undergoing so as to speed up the processing of the mRNA (Gerber and Shilatifard 2003; Sims et al. 2004a, b). The unprocessed or partially processed mRNA, also known as pre-mRNA, is degraded, while mature mRNA is the completely processed mRNA.

## Eukaryotic Pre-mRNA Processing

Even though the prokaryotic mRNAs are essentially mature upon transcription, the eukaryotic mRNA needs extensive processing to promote their maturation. One of the important pre-mRNA processing techniques utilized to mature eukaryotic mRNA is 5' cap addition which is coupled to transcription and is critical for recognition by the ribosome and protection from RNases, splicing by which pre-mRNA is modified by removal of noncoding sequences called introns, editing where sometimes the sequence of the mRNA is edited and results in

modification of its nucleotide composition, and polyadenylation which is the covalent linkage of a polyadenylyl moiety to an mRNA molecule at 3' end mostly. It aids in protecting mRNA from degradation by exonucleases, transcriptional termination, and export of the mRNA from the nucleus. Prokaryotic mRNA polyadenylation however facilitates exonucleolytic degradation (Gerber and Shilatifard 2003; Jurado et al. 2014; Xiang et al. 2014).

## Transport

Another difference between eukaryotes and prokaryotes is mRNA transport. Because eukaryotic transcription and translation are compartmentally separated, eukaryotic mRNAs must be exported from the nucleus to the cytoplasm. Mature mRNAs are recognized by their processed modifications and then exported through the nuclear pore.

## Translation

Translation is initiated just after transcription in prokaryotes because they do not require processing or transporting. Thus, prokaryotic translation is coupled to transcription and occurs co-transcriptionally. Nonetheless, eukaryotic mRNA is first processed and thereafter transported to the cytoplasm which is then translated by either free floating ribosomes or those attached to endoplasmic reticulum by signal recognition particle (Dever and Green 2012; Hinnebusch et al. 2016; Kozak 1983). Therefore, unlike prokaryotes, eukaryotic translation is not directly coupled to transcription.

## Degradation

After a certain amount of time, the message is degraded by RNases. The limited lifetime of mRNA enables a cell to alter protein synthesis rapidly in response to its changing needs. Different mRNAs within the same cell have distinct

lifetimes (stabilities). In bacterial cells, individual mRNAs can survive from seconds to more than an hour; in mammalian cells, mRNA lifetimes range from several minutes to days. The greater the stability of an mRNA, the more protein may be produced from that mRNA. The presence of AU-rich elements in some mammalian mRNAs tends to destabilize those transcripts through the action of cellular proteins that bind these motifs. Rapid mRNA degradation via AU-rich elements is a critical mechanism for preventing the overproduction of potent cytokines such as tumor necrosis factor (TNF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) (Shaw and Kamen 1986). Base pairing with a small interfering RNA (siRNA) or microRNA (miRNA) can also accelerate mRNA degradation (Nilsen 2007).

## Applications of mRNA

Application of mRNA in its native and modified form is colossal, and recently the concept of mRNA pharmacology has been introduced which involves ex vivo and direct vaccination of in vitro transcribed (IVT) mRNA into the cell. These methods can be used for genome engineering, genetic reprogramming, T cell and dendritic cell mRNA-based immunotherapies to treat cancer and infectious diseases, replacement of proteins, telomerase regiments to treat allergies, and other protein replacement therapies (Grimm and Kay 2007; Sahin et al. 2014; Vallazza et al. 2015; Van et al. 2015). The introduced mRNA is translated by the cells' own translational machinery; however, the introduction of mRNA does not alter the physiological state of the cells due to its transient and non-mutagenic effect. Moreover, while protein synthesis, there is no intervention in the human genome because mRNA does not integrate into the genome and basically does not even require entering the nucleus to get translated. Therefore, mRNA has rightly been called the next-generation therapeutics.

## Conclusion

The mRNA of several bacteria and bacteriophages is polycistronic, whereas in eukaryotes, it is monocistronic in nature. Posttranscriptional modification of prokaryotic mRNA is very little; on the other hand, eukaryotic mRNA undergoes major posttranscriptional modification which includes polyadenylation at 3' end of mRNA, capping at 5' end by condensation of guanylate residues and splicing of introns from heterogeneous mRNA. Life span of prokaryotic mRNA is very short in comparison to eukaryotic mRNA, and like all other biomolecules, RNA also undergoes degradation after its useful life.

Humans feel doubt and uncertainty. They often respond adaptively to these feelings by seeking additional information. In essence, they *GOOGLE™*. Humans' responses to mental states like uncertainty have grounded an enormous research literature on metacognition (Benjamin et al. 1998; Dunlosky and Bjork 2008; Flavell 1979; Koriat 1993; Nelson 1992; Schwartz 1994).

Metacognition occurs when cognitive processes oversee and guide other cognitive processes. Nelson and Narens (1990) provided a useful theoretical perspective on metacognition (Fig. 1). They differentiated cognitive processes at a first-order, object level and a second-order, meta level. The object level registers stimuli, retrieves memories, and so forth. The meta level monitors the first-order processes to judge their accuracy, relevance, and sufficiency to the task at hand. It also controls the first-order processes, directing them toward perhaps more productive and facilitating approaches. The monitoring processes (feelings of knowing, judgments of learning, confidence judgments, etc.) and the control processes (time allocation, strategy selection, etc.) are shown in Fig. 1 (top and bottom, respectively). The animal-metacognition literature has begun to explore both these monitoring and control functions of metacognition within nonhuman animals (hereafter, animals).

Metacognition clearly reveals the sophistication of human cognition. It shows hierarchical levels in mind, as second-order metacognitive processes regulate first-order cognitive processes.

**Meta-cognition, Fig. 1** A theoretical framework for research on metacognition, showing examples of process-monitoring capacities above and process-control capacities

below. (From Nelson and Narens 1990. Copyright 1990 by Elsevier Ltd, Reprinted with permission)

It shows humans’ conscious awareness of their own cognitive processes (Nelson 1996; Koriat 2007) – metacognitive states often reside within awareness and can be declared to others. In fact, research on human metacognition depends on these declarations. Metacognition is also intimately linked to humans’ self-awareness (Gallup 1982), because mental states like uncertainty are distinctly personal and self-owned (*I* don’t know; *I* can’t decide). Indeed, Gallup thought that a cognitive-awareness like metacognition was one of the fundamental cognitive capacities revealed by success in the mirror-dye test. Thus, readers should note that the area of animal-metacognition research is closely allied to the research areas on animal consciousness and animal self-awareness.

Yet because metacognition is such a sophisticated capacity, mightn’t it be a uniquely human achievement? Given this question’s importance, Smith and colleagues inaugurated a new area

of research on animal metacognition (Smith et al. 1995, 1997, 1998, 2003). The field has grown enormously and achieved substantial theoretical success (e.g., Basile et al. 2015; Beran et al. 2013; Call 2010; Couchman et al. 2010; Foote and Crystal 2007; Fujita 2009; Kornell et al. 2007; Paukner et al. 2006; Roberts et al. 2012; Smith et al. 2013; Suda-King 2008; Sutton and Shettleworth 2008; Templer and Hampton 2012; Washburn et al. 2006; Zakrzewski et al. 2014). Many innovative, distinguished colleagues have contributed to this research area. This listing can only be illustrative. In this entry to the encyclopedia, we summarize the research area of animal metacognition, discussing empirical progress, theoretical challenges surmounted and remaining, and the relationship of this work to other areas in comparative psychology.

The original researchers in this area faced the problem that human metacognition paradigms

do not suit animals, for their phenomena are based in verbal self-reports about feelings of knowing (FOKs in the literature), judgments of learning (JOLs), and tip-of-the-tongue experiences (TOTs) (see Brown 1991; Hart 1965; Smith et al. 1991). As matters stand presently, such self-declarations cannot be a viable part of the empirical dialog between animal participants and human practitioners.

Therefore, early animal metacognition research focused on a comparative uncertainty paradigm. There are two basic requirements for creating such a paradigm. The first is to create perceptual/cognitive/memorial difficulty for the animal – using difficulty to stir up something like an uncertainty mental state in animals' minds. This requirement caused an interesting conflict in the original dolphin-metacognition research, because the dolphin's trainers did not want to cause the animal the stress of difficulty and uncertainty. This was solved by opening the animal's enclosure to the Gulf of Mexico during testing sessions. He could relieve any trial stress by going for a walkabout in the Gulf – all the way to Dry Tortuga if he wished. But always, he quickly came back to join his trainer, the task, and the fish (Smith et al. 1995).

Presenting difficult trials is not sufficient for exploring animal metacognition. Many times animal psychophysicists have brought animals to their discrimination thresholds, the point where animals cannot know which stimulus event is occurring and which primary response to make. At threshold, their response curves for the two primary responses cross, demonstrating clearly that they do not know. These tasks feature difficulty. They show animals facing response conflict given balanced response strengths. They might reflect an animal feeling something like uncertainty. But, they can't show metacognition. This capacity is hidden by allowing only primary responses that map to the two perceptual input classes, and by denying the animal any way to comment on mental states like uncertainty or to respond to them effectively.

One solution is to hope that animals make ancillary behaviors, making observable their uncertainty or conflict on threshold trials. These ancillary behaviors do occur sometimes. They even made behaviorists somewhat uncomfortable

because they seemed to show that animals were in mental turmoil on difficult trials. Tolman even suggested that these ancillary behaviors – that he called “lookings or runnings back and forth” (Tolman 1938, p. 27) – could operationalize animal consciousness for the behavioral researcher (Tolman 1927).

However, it is hit or miss to depend on ancillary behaviors like these. Uncertain/puzzled humans might scratch their heads, uncertain monkeys might not, and uncertain dolphins would not! The behaviors might not be observable across species or comparable across species. Surely animals in different species may react differently when facing uncertainty. Accordingly, the best strategy in comparative metacognition research has been to give animals of different species the same behavioral response, letting them report on or deal with the difficult situation. This becomes the second requirement of an animal-metacognition paradigm – to give animals a third response that lets them cope with trial difficulty by declining to complete any trials they choose. This third response has now come to be called the Uncertainty Response (UR) in the literature. With this response available, one may see the animal adopt this reasonable strategy: to use the UR selectively when error or failure on the primary perceptual or cognitive task seems likely. To carry out this strategy, animals must identify, if they can, the occasions on which failure is likely.

The early history of this literature has been well reviewed (e.g., Smith et al. 2003; also entry *The Uncertainty Paradigm in Animal-Metacognition Research* in this Encyclopedia). Still, one example of the early paradigms will be described here to establish the literature's theoretical context. Smith et al. (1997) placed rhesus macaques (*Macaca mulatta*) in a psychophysical threshold task. Their use of a threshold task may be theoretically important. Macaques saw unframed boxes on their computer screens that could vary in their internal density of lit pixels. True Dense trials (exactly 2,950 lit pixels) occurred about half the time. Sparse boxes (ranging from 450 to 2949 pixels) occurred about half the time. Macaques used a joystick to

move a cursor to touch the pixel box (Dense response) or an S (Sparse response) to positively identify members of these two perceptual classes. Approaching threshold, as Sparse trials grew much denser, they became hard to identify. In turn, Dense trials became confusable with these Sparse trials, and also grew difficult. So, macaques were also allowed to make URs by moving the cursor to a Star. This let them decline to complete the present trial, end it, and receive a new, easy trial.

In Fig. 2, the Sparse and Dense discrimination curves cross at about 2,650 pixels. Here, macaques demonstrably could not tell Sparse from Dense. They didn't know. They couldn't know. But the question is whether they were in touch with some psychological signal that would let them monitor this uncertainty and manage it. And they were. The bold UR curve shows that they correctly assessed when they were at risk for error in the primary discrimination, and they selectively declined to complete those trials. The peak of the UR performance curve lies just over their threshold region. If their performance was metacognitive, then we could say that animals were monitoring the difficulty of trials and appreciated that at threshold they were in decisional trouble. But there are other possible signals

macaques might have been reacting to, and we will discuss these shortly.

Humans performed highly similarly (Smith et al. 1997). There is an isomorphism between humans' and monkeys' URs that is potentially theoretically meaningful. The main difference is that humans tend to use the UR less generously and somewhat reluctantly. The interesting explanation for this is that humans view the UR as a cop-out compared to a strong, affirmative Sparse or Dense response. It is interesting that the UR feels psychologically distinctive to humans – less affirmative, weaker – and this also has theoretical significance. Humans also explicitly declared that their URs were based on their conscious uncertainty on difficult trials. They knew they didn't know – consciously. To them their three responses meant: That's Sparse, That's Dense, I don't know. The UR in this task is an index of humans' meta-cognition. Macaques use the UR identically. The theoretical foundation was laid to consider whether that response can index metacognition in animals, too.

So what were macaques thinking or reacting to? Did they self-reflect on mental states like doubt? This would be a high-level psychological signal akin to metacognition. Or had they simply grown avoidant of the threshold stimuli that

**Meta-cognition, Fig. 2** A monkey's performance in the uncertainty paradigm used by Smith et al. (1997). The horizontal axis indicates the density of the trial. For 2,950-pixel trials – those trials plotted to the far right of each curve – the Dense response was correct. For all trials with lesser densities/fewer pixels, the Sparse response was

correct. The percentages of Dense and Sparse responses are shown (dashed lines). The percentage of trials receiving the uncertainty response at each trial level is shown in the solid line. (Adapted from Smith et al. 2003. Copyright 2003 by the Cambridge University Press)

often brought errors, time-outs, and reduced rewards? This stimulus aversion would be a low-level stimulus cue. If this were the explanation, then low-level explanations were possible for the macaques' "metacognitive" performances. That is, they could be explained associatively, by reinforcement learning, if animals' URs are cued by stimuli or shaped by reinforcement. Therefore, the early animal-metacognition paradigms were debated sharply. Indeed, one will see in this entry that the animal-metacognition literature has been dominated by the associative-metacognitive debate (Basile and Hampton 2014; Basile et al. 2015; Carruthers 2008, 2014; Hampton 2009; Jozefowicz et al. 2009a, b; Le Pelley 2012, 2014; Smith 2009; Smith et al. 2008, 2009a, b, 2012a, 2014a, b; Staddon et al. 2007).

The story of this literature, in the hands of many inventive colleagues, has been one of dramatic empirical progress, and notable theoretical development in resolving this debate. Research has progressively lifted the phenomena of animal metacognition above traditional notions of stimulus control and beyond traditional ideas of reinforcement-based learning. It has raised the possibility of higher-level systems and processes in animal learning. It may have even grounded the development of methods to explore animals' conscious awareness. It has refined theoretical ideas in comparative psychology, and bent the arc of the field's theoretical discourse. This entry summarizes briefly the story of the literature.

Given early results like those shown in Fig. 2, associative-learning theorists were quick to supply various possible low-level explanations. However, these associative accounts soon met difficulty. For example, one sees immediately that a threshold stimulus – by definition – is terribly indeterminate. Because it equally suggests either of two responses (e.g., Sparse, Dense), it recommends neither. It is a very difficult kind of a stimulus to envision triggering a low-level reactive response. Moreover, it is most unclear whether the region at threshold could in any way be considered a third, intermediate stimulus between Sparse and Dense to which animals might react associatively. In fact, behavioral analysts had already grappled with the difficult

stimulus-control problem presented by threshold stimuli, concluding that the threshold state changes profoundly the nature of stimulus control and associative behavior (Boneau and Cole 1967; Commons et al. 1991; Davison et al. 1985; Miller et al. 1980; Terman and Terman 1972). So, is responding to a threshold state still associative responding, or have we already taken a step toward higher-level cognitive processing? Even though the early studies fairly deserved the criticism they received, it was quickly clear that stimulus-based accounts were less transparently available than it had first seemed.

Complementary research took uncertainty paradigms still farther from traditional ideas of stimulus control. In Shields et al. (1997), for example, macaques responded uncertain when they judged they were not able to complete trials in an abstract, simultaneous Same-Different task. This task is known to be cognitively sophisticated and derived – organisms are not responding to the concrete stimuli presented, but to the abstract relation instantiated by the combination of the two stimuli. Just for this reason, true Same-Different performances occur in only a handful of cognitively sophisticated species. Sameness is not a stimulus; neither is Differentness. Yet macaques were able to make URs selectively for the same-different trials that were most difficult because they were poised at their threshold for discriminating Same and Different. Their performance profiles correlated up to 0.97 with human performance in the equivalent task. Possibly relational-judgment uncertainty transcends associative responding, crossing a threshold to demonstrate animals' higher-level uncertainty-monitoring capability.

The associative-learning construct was challenged more strongly when the "stimulus" to be judged was present only in the animal's memory. In Hampton's (2001) elegant study, monkeys declined to complete tests of their memory when they judged that their available memory traces were faint or questionable. Figure 3 shows that at longer delays, as sample memory became fainter, monkeys made URs more often, as though they were monitoring the metacognitive signal of fainter memory and responding to it

**Meta-cognition, Fig. 3** A macaque's performance in the uncertainty paradigm used by Hampton (2001). The horizontal axis indicates the length of the retention interval before matching could occur. The percentages correct are shown for memory tests completed when the memory test was required (dashed line) or optional and intentionally chosen by the macaque (dotted line). The percentage of trials receiving the uncertainty response is shown in the solid line. (Adapted from Hampton 2001. Copyright 2001 by The National Academy of Sciences)

appropriately. Hampton also showed that at longer delays, when monkeys did not respond uncertain, but rather chose to complete the memory test, their performance was quite high. This result is consistent with the monkeys' following a metacognitive signal that told them they still remembered the sample on that trial. This performance difference between Chosen trials (selected for completion by the animal) and Forced trials (fended off by the UR) has become an important finding in the memory tasks in this literature. In these experiments, there was no objective stimulus that could control behavior. Rather, animals had to consider whether they remembered the previous sample. It is quite doubtful that a monitored, faint memory should be considered an associative stimulus that controls behavior. Performance in this task seems to depend instead on some cognitive process like memory monitoring.

Washburn et al. (2010) gave the Hampton task a telling twist. They presented shapes far in a monkey's left or right visual periphery, so that the to-be-matched sample might be represented more quickly and fully in the opposite cerebral hemisphere. The macaque sometimes received

transcranial magnetic stimulation (TMS) to the left or right cortex during the forgetting interval. The TMS disrupted visual working memory temporarily. With no TMS, the macaque matched well and made few URs. With sample presentation and TMS concordant (stimulus left periphery, TMS left cortex), the result was the same, because the TMS had largely spared the relevant memory contents. But with sample presentation and TMS opposed (stimulus left periphery, TMS right cortex), the monkey matched poorly and made many URs. In a sense, the TMS stole the contents of the animal's visual working memory after stimulus presentation was complete. The remarkable result is that the monkey noticed the theft, and made URs adaptively in that case. Clearly, he was monitoring an internal signal regarding a psychological state of lost memory.

Through this period of research, it gradually became clear that the normal mechanisms of associative learning could simply not explain the phenomena of uncertainty responding in the animal-metacognition literature. Rather, it seemed that animals might be bringing some higher-level cognitive strategies to bear on the tasks being studied. In one capstone comment summarizing this literature, Carruthers and Ritchie (2012, p. 76) concluded that "this body of work, taken as a whole, cannot be explained in low-level associationist terms, as involving mere conditioned responses to stimuli." In a capstone experiment, Basile et al. (2015) systematically explored 7 possible associative hypotheses about macaques' URs in memory-monitoring tasks. They found no evidence supporting these hypotheses. Rather, they consistently found evidence supporting the metacognition or memory-monitoring hypothesis. Basile et al. (2015, p. 85) concluded that monkeys "can use memory strength as a discriminative cue for information seeking, consistent with introspective monitoring of explicit memory."

Accordingly, researchers began to establish the diagnostic features of these higher-level strategies, which appeared to show many aspects of controlled and deliberate cognition by animals. Smith et al. (2010) showed that monkeys could make adaptive URs in four different tasks simultaneously when trials of these tasks were

interleaved randomly. URs were apparently responsive to a general psychological signal of uncertainty that was not restricted to one stimulus domain at a time. Washburn et al. (2006) showed that macaques would make URs on the first trial of novel tasks, showing that the signal of uncertainty they were monitoring was available in new stimulus domains that had never been trained or reinforced. In another indication of the cognitive flexibility grounding monkeys' confidence/uncertainty judgments, Morgan et al. (2014) tested the transfer of these judgments between retrospective and prospective versions of an uncertainty task. One monkey was able to transfer immediately, from reporting lack of confidence after a trial response had already been completed, to reporting unwillingness to engage the trial before a trial response was made. Finally, Zakrzewski et al. (2014) showed that monkeys could flexibly, from trial to trial, adjust their willingness to complete difficult trials, or to decline those trials, based on the number of reward tokens they stood to lose from an error. That is, monkeys, just like humans, made a modified form of UR differentially based not only on trial difficulty but also on the risk they faced. In psychophysical terms, they widened their uncertainty region as their accumulated rewards increased, so that they protected themselves more generously against a possible error that would cost them all those rewards. Haun et al. (2011) showed a similar flexibility in ape species.

Gradually, the theoretical climate changed, so that theoretical consensus emerged that animals were not only bringing high-level cognitive strategies to bear on the literature's tasks, but possibly also sometimes bringing metacognitive strategies. Sutton and Shettleworth (2008, p. 266) concluded that "metamemory, the ability to report on memory strength, is clearly established in rhesus macaques (*Macaca mulatta*) by converging evidence from several paradigms." Fujita (2009, p. 575) concluded that "evidence for metacognition by nonhuman primates has been obtained in great apes and old world monkeys." Roberts et al. (2009, p. 130) concluded that "substantial evidence from several laboratories converges on the conclusion that rhesus monkeys

show metacognition in experiments that require behavioral responses to cues that act as feeling of knowing and memory confidence judgments." Our theoretical judgment is that this consensus is clearly justified. However, this judgment does not imply that nonhumans share all aspects of humans' metacognitive capacity, or that animal metacognition is self-imbued and self-conscious in the ways that human metacognition is. There can still be important differences across species that remain to be investigated.

Only a few times in comparative psychology has there been such a careful and systematic evaluation made of the sufficiency of associative-learning processes in explaining animals' behavioral performances. This evaluation has been especially influential within comparative psychology because of the clear lessons it teaches: Associative interpretations are sometimes insufficient to capture a field's phenomena, animals sometimes transcend associative mechanisms, showing higher-level, deliberate cognitive strategies instead. Therefore, comparative psychology must also turn to the problem of characterizing the nature and cognitive level of those higher-level strategies.

In fact, Smith and his colleagues tried to characterize these cognitive strategies (Smith et al. 2012a, b, 2003). This was a difficult problem because comparative psychology lacked models and descriptions that transcended associative learning. So they began with an admittedly questionable analogy to human cognition. In uncertainty tasks, the essence of the information-processing problem is to be facing an uncertain threshold stimulus or an indeterminate memory trace. By definition, the animal will then experience equivalent response tendencies and reward expectations regarding both primary responses. Response in this case cannot be adjudicated by reinforcement-based, conditioned response tendencies. The animal will be frozen between responses like the philosophical donkey facing two haystacks. Some other decisional process would have to step in to referee the behavioral close call and break the tie. Shiffrin and Schneider (1977) described the cognitive processes that could do so. They agreed that because ambiguous

mental representations map equally to multiple behavioral responses, those representations cannot be the organism's behavioral indicator. Accordingly, they thought responses made under uncertainty could not reflect low-level, automatic processes. Instead, they thought the organism would adopt higher, controlled cognition to resolve the indeterminacy and choose adaptive behavioral solutions. These controlled processes would be slow, deliberate, and serial in nature by Shiffrin and Schneider's theoretical description. Atkinson and Juola (1974) made the analogous claim about the resolution of indeterminate memory traces. This analysis applies even to the threshold phenomena shown in Fig. 2, another reason why one should not too quickly dismiss these early performances as purely associative and reactive.

In interesting ways, this higher-level description of animal-metacognition performances has proved out and is being clarified with more operationalizable cognitive constructs. For example, Smith et al. (2013) reconsidered monkeys' performance in the Sparse-Uncertain-Dense task already described in this entry (Fig. 2). However, in some conditions, they gave monkeys a concurrent working-memory load to sustain while they performed the Sparse-Dense trials. The memory load possibly served to occupy macaques' active cognitive resources, diverting those resources away from the discrimination task. Smith et al. hypothesized that URs, if they are a higher-level decisional response, might be especially vulnerable to this manipulation, as they would depend on these cognitive resources. But they suggested that Sparse and Dense responses could be low-level, associative, stimulus reactive, and not affected by the memory load. These results obtained. Concurrent tasks disrupted macaques' URs far more than their Sparse or Dense responses. Interestingly, Schwartz (2008) found that for humans, too, memory load strongly interfered with metacognitive judgments, above all sharply decreasing tip-of-the-tongue experiences. It is a significant theoretical insight if monkeys' metacognition and working memory use similar cognitive resources, as proposed by Schwartz for humans.

Smith et al. (2013) presented an additional notable dissociation when they gave monkeys an allied Sparse-Middle-Dense task. In this case, the Middle response was correct for an objective range of intermediate density impressions – in essence the same range that should also occasion the UR in the other task. But Middle responses to Middle stimuli were immediately rewarded, clearly supporting reinforcement-based, associative learning. And now, Smith et al. found that Middle responses, just like Sparse and Dense responses, were minimally affected by the cognitive load. Monkeys can react automatically to identifiable stimulus impressions, even with memory resources occupied. What they seem less able to do without those resources is to monitor the still, small psychological signal that indicates they don't know.

A significant benefit of the newer theoretical perspectives on animal metacognition is the synergy it creates with human research, and in particular with the literature on human cognitive neuroscience. For example, Paul et al. (2015) described the distinctive psychological circuits underlying uncertainty responding using rapid event-related fMRI. They used the Sparse-Uncertain-Dense task once again. They showed that the neural activity patterns recruited during humans' URs are distinctively different from those recruited during humans' primary perceptual responses (Sparse, Dense).

Figure 4 (top) shows the simple activation pattern when participants chose correct Sparse or Dense responses instead of making URs. The activity pattern was elementally simple, consistent with the interpretation that Sparse and Dense responses are first-order behaviors in which identifiable visual stimuli elicit well-associated behavioral responses.

In contrast, Fig. 4 shows the complex activation pattern when participants chose URs instead of Sparse-Dense responses. Uncertainty responding activated a much more elaborate cognitive-control network. This result is consistent with the idea that URs are the output of controlled, decisional cognitive processes – the idea to which cognitive experiments were already pointing. Of course, this is a human experiment

only. But it exhorts comparative psychologists toward eventual replication with monkeys. It also starts to map the field's cognitive-science constructs to their neuroscientific architectures, explaining why the response to uncertainty is so distinctive psychologically.

Smith and Church (2017) contributed a theoretical review to this area. They described instances in which small task changes (just like the change from Uncertain responding to Middle responding discussed above) alter sharply the cognitive psychology of tasks – sometimes affecting in concert the level of awareness, the

declarative nature of knowledge, the dimensional breadth of knowledge, and the brain systems that organize learning. These changes reveal dissociable learning processes that a unitary associative construct cannot explain but that a multiple-systems framework can explain. They urged comparative scientists to bring this multiple-systems approach to comparative studies, even though it means acknowledging that animals may have systems of cognitive processing that are parallel to humans' systems of declarative and explicit cognition. Work by Robert Hampton and his colleagues is proceeding along similar, dissociative

lines (Anderson et al. 2014; Basile and Hampton 2013; Tu and Hampton 2012). It is interesting that two laboratories focusing on this new multiple-systems theoretical perspective in comparative psychology have emerged from long practice in the animal-metacognition literature.

From the original associative criticisms of the UR by monkeys, to new systems perspectives in comparative psychology, to possibly explicit-declarative levels in animal minds, the animal-metacognition literature has traced a constructive journey and fostered theoretical development in comparative psychology.

This entry would not be complete without discussion of metacognition research on other vertebrate species. One can see the theoretical utility behind cross-species research. If, as one theoretical possibility, uncertainty responding were simply associative and stimulus reactive, then we could expect to observe metacognitive performances (so-called) spread broadly across species, because many animals condition and learn associatively, and should do so in metacognition tasks as well. However, if, as another theoretical possibility, some animals monitor uncertainty states like uncertainty and doubt in higher-level ways, then we could expect to observe these performances spread narrowly across species. And, of course, this cross-species research would also illuminate the emergence during cognitive evolution of capacities like cognitive self-awareness.

With the clear demonstration of successful uncertainty monitoring in Old-World rhesus macaques, research quickly turned to examining monitoring abilities in New-World monkeys, like capuchins. Evidence for the ability of these monkeys to monitor their uncertainty has been harder to find, and the field has largely come to the consensus that their monitoring ability is weaker than that of macaques (e.g., Beran et al. 2009, 2014; Fujita 2009).

Fujita (2009) gave capuchin monkeys a variation of the delayed matching task along with the UR on some trials. In one experiment, two capuchins made URs more often after longer forgetting intervals, consistent with the idea that they knew they had forgotten the sample they were to match.

One of the two showed the advantage of Chosen trials over Forced trials that has already been discussed. However, Fujita conducted additional experiments, and in the end he concluded that these monkeys are expressing a faint and fragile metacognitive capacity.

Beran et al. (2009) tested capuchin monkeys in a Sparse-Uncertain-Dense psychophysical uncertainty paradigm and found that even with extremely long time-outs for incorrect answers only one capuchin showed any sign of ever using the UR to fend off difficult trials. However, when they used the Sparse-Middle-Dense paradigm described earlier, the capuchins had no problem learning to correctly discriminate the middle items. They concluded that capuchins do not have a robust metacognitive ability to monitor their uncertainty.

In follow-up work, Beran et al. (2014) used a six-choice psychophysical discrimination (in contrast to the usual two-choice discrimination) in both capuchins and macaques. This reduced the probability of randomly guessing the correct answer from 50% to 17%. Under these circumstances, all the macaques used the UR on the difficult trials, and multiple capuchins also used the UR appropriately. The researchers concluded that capuchins potentially have the ability to monitor uncertainty, but it is harder for them than for the Old-World monkeys, perhaps because they are more impulsive and less risk averse.

Pigeons and their researchers have also made a strong contribution to research in this area. For example, Inman and Shettleworth (1999) evaluated pigeons' metamemory capacity using an approach like that in Hampton (2001). Pigeons given longer forgetting intervals in matching trials demonstrably forgot what they should match (Fig. 5, dashed and dotted lines). Yet they barely made more URs after long delays, though avoiding the long-delay trials would have been optimal (bold line). The pigeons don't seem to have access to a psychological signal indicating that they have probably forgotten the sample and they should respond uncertain to decline the trial.

Inman and Shettleworth also analyzed the trials that pigeons chose affirmatively to complete (by NOT responding uncertain). A metacognitive

**Meta-cognition, Fig. 5** Pigeons' performance in the uncertainty paradigm adopted by Inman and Shettleworth (1999). (Data graphed with permission from Inman and Shettleworth 1999. Copyright 1999 by American Psychological Association)

animal ideally would be monitoring some psychological signal that told them that the relevant memory trace was still present and active, so that it was safe to complete the memory test. Yet pigeons did not show stronger matching performance when they chose to complete matching trials than when they were forced to complete them (Fig. 5, dashed and dotted lines). In these aspects of performance, pigeons hardly expressed any metacognitive capacity. Comparing Fig. 5 to Fig. 3, one sees that pigeons, evidently not expressing a metacognitive capacity in these tasks, were quite different than monkeys, who do express that capacity.

Sutton and Shettleworth (2008) replicated the pigeon findings in several experiments using converging methods. They still found that pigeons were a strong comparative NO in the area of metacognition. Shettleworth and her colleagues made a very strong contribution by systematically building this negative evidence – sometimes the rewards of our field obstruct this important kind of research. At least one must conclude that pigeons have great difficulty expressing the key features of metacognitive performance. Nonetheless, research continues to find the right contingencies under which pigeons may show a semblance of monkeys' metacognitive performances. These efforts are highly appropriate, for

they might suggest the very earliest forms that ancestral cognitive self-awareness assumed, and how it arose from purely associative processes (Adams and Santi 2011; Zentall and Stagner 2010, 2011).

Similar studies with rats have produced results more indicative of metacognition within a non-primate mammal. For example, Foote and Crystal (2007) conducted a study akin to the psychophysical perceptual studies described earlier in this entry. Rats performed a discrimination among temporal durations. On some trials, rats could make a UR to decline to complete it, which they should do if the trial was difficult because it is near the Short-Long break point of the duration continuum. On other trials, rats were required to complete the discrimination trial. This technique of comparing performance on Forced and Chosen trials is a very innovative and revealing approach that we have seen adopted by several researchers already.

Foote and Crystal found that rats did respond Uncertain most on the durational stimuli nearest the Short-Long break point of the discrimination. They also found that rats performed more accurately on Chosen trials than on Forced trials, as though they were monitoring a felicitous psychological signal indicating an appropriate expectation of responding correctly. This was the first demonstration of possible metacognition by rats in the perceptual tasks of this literature.

The experiment by Foote and Crystal (2007) remains an extremely interesting, sophisticated experiment. It is fair to say that Crystal later became skeptical about the results that they had obtained. He was influenced by Smith et al.'s (2008) theoretical article in which they noted some cautions necessary before fully and safely concluding metacognition from performance in tasks like theirs. We note that we do not necessarily share Crystal's skepticism, given what we have said about the special character of threshold tasks and about the special psychological character of the threshold state.

Templer et al. (2017) adopted a delayed matching-to-sample paradigm akin to those tested by Hampton with macaques and by Shettleworth with pigeons. The rats performed an odor memory

task. They could make a UR to decline the memory tests they wished. Templer et al. also compared trials on which rats chose to complete the test to trials when they were forced to complete the test. Rats did show a performance advantage on chosen trials, possibly an important symptom of cognitive monitoring. Rats also showed continued appropriate use of the UR under conditions that were designed to strengthen or weaken their memory traces. This was the first demonstration of possible metacognition by rats in the matching-to-sample tasks of this literature. Probably the convergence of the results in Foote and Crystal (2007) and Templer et al. (2017) suggests the reasonable likelihood that rats are expressing the beginning form of cognitive self-awareness.

If the cognitive origins of metacognition lie before the primates, perhaps one can see why. There must be times when animals face difficulty and uncertainty in the natural ecology. Those cases, by definition, are when there hasn't been training, or when there is response conflict, or when the balanced forces of conditioning can't resolve an adaptive behavior. Instead, the adaptive behavior must be selected using some other mechanism, perhaps at a higher cognitive level. It is simply logical that some animals would have benefited from having – that is, from evolving – an uncertainty-monitoring mechanism like that macaques clearly have. Even James (1890/1952) noted the particular advantage that conscious uncertainty could confer on organisms facing difficult, dangerous, and uncertain situations. Now, to be sure, the potential benefits from evolving metacognition do not guarantee that animals would have evolved metacognition. It isn't known how difficult it is for cognitive systems to arrive at forms of decisional response selection – or perhaps forms of mental self-reflection – that are above and beyond stimulus reaction and reinforcement learning (Smith et al. 2003).

This entry would also not be complete without addressing the elegant research that has explored animals' metacognitive control over cognition, the bottom of the metacognitive capacity expressed in Fig. 1. The question here is whether animals, beyond realizing in a sense that they are in cognitive difficulty, can also change

and guide their information processing down more facilitative pathways.

Research in this area is typified by the elegant information-seeking paradigm of Call and his colleagues. For example, Call and Carpenter (2001, also Call 2010; Suda-King 2008) used a naturalistic uncertainty task (i.e., which opaque tube contains food) in tandem with an information-seeking response (i.e., visually checking to find out where the food is). Sometimes apes saw the food placed in the containers. On those trials, they retrieved the food without seeking additional information. On other trials, they did not see the placement of the food. On those trials, they made information-seeking responses (bending down to inspect the barrels of the food tubes). It is a notable feature of this design that the two situations are identical in the perceptual and potentially associative cues that are presented to the animal – the setup, the tubes, everything is identical. The only distinguishing feature lies in the animals' self-awareness of knowing where the food is. These tasks come close to logically requiring animals to respond to their state of knowledge.

In an engaging extension of this research, Call (2010) showed another very human thing about chimpanzees' information seeking. He found that when the food tubes contained a very highly desired food item, the chimpanzees would check the tube to make sure they had it right **EVEN IF THEY HAD CLEARLY SEEN THE HIDING**. Call likened this to the human in an international airport terminal who checks their passport in their pocket for the 14th time, because it is really important not to spend your vacation time in some country's detention facility because you forgot a travel document.

Beran et al. (2013) confirmed the cognitive sophistication of chimpanzees' information seeking by raising the ante on Call's task to the symbolic lexical level. Chimpanzees were given a task in which they had to identify on their lexicon keyboards the identity of a hidden food in order to obtain it. They got the food if they supplied its correct lexical label. They could report the food's name directly on their nearby keyboard. Or, they could take a significant route detour in order to

first inspect the opaque container in which the food item was hidden. On some trials, they saw the food placed in its container. Then they often immediately labelled it. On other trials, they did not see the food's placement. Then they often detoured to look inside the container before naming. They sought additional information just when they knew they lacked sufficient information to complete the trial correctly.

The research area on metacognitive control has also produced strong and intriguing species differences. For example, Basile et al. (2009) tested capuchin monkeys (*Cebus apella*, a New World monkey species) in Call and Carpenter's (2001) food-tube paradigm. In an interesting failure to express the expected metacognitive capacity, they found in one experiment that only one of five monkeys showed the pattern of searching more often when the food-hiding event had not been seen. In later experiments, capuchins were slightly more successful. But Basile et al. concluded that overall capuchins were showing dubious evidence of having this metacognitive capacity.

In Paukner et al.'s (2006) converging study, some capuchin monkeys did show evidence of visual inspections before food-tube selection. Yet capuchins also showed evidence of visual inspections for transparent tubes in which the food was clearly visible. They also searched bent tubes, even though these searches were futile because they could not yield any useful information. Paukner et al. judged that, unlike humans, apes, and macaques in related studies, capuchin monkeys showed a relatively weak expression of this metacognitive capacity.

Roberts et al. (2009) conducted fascinating information-seeking studies with pigeons. The birds participated in a matching-to-sample task. However, the sample was initially occluded, and pigeons needed to make a sample-reveal response to see it. Clearly, if you don't see the sample, you will be at chance in trying to match it. Remarkably, pigeons had a controlling tendency just to attempt the match, even though the match now occurred without their having seen the sample and without any relevant information to support the match. Roberts et al. (p. 129)

concluded that "The findings of all of these experiments suggest the absence of metamemory in pigeons."

We were extremely interested in this strong negative result, and we saw a chance to confirm by this converging paradigm the macaque–pigeon species difference that has already been discussed in this entry. So we studied information seeking by capuchin monkeys and rhesus macaques in a task much like that of Roberts et al. (2009). Rhesus monkeys immediately understood that if you want to match correctly, you have to wake up the sample. Even capuchin monkeys were substantially successful at making this basic information-seeking response. In more detailed testing, though, the capuchins exhibited definite weaknesses in information seeking compared to macaques (Beran and Smith 2011).

Once again, the pigeon–macaque dissociation testifies to the distinctive cognitive sophistication of metacognitive responses like information seeking. If the situation contained a patent temporal, or stimulus, or other associative cue, pigeons might well learn to respond reactively to that. In fact, the matching task did contain a strong stimulus of an occluded sample, yet still that did not cue successfully the sample-reveal response. It did not do so even after extensive training in which the birds were required to wake up the sample, and got to see how much their matching performance improved. Pigeons just aren't finding the internal signals of not knowing, of needing information, and so forth. Macaques appear to find and respond to those psychological signals easily and naturally. Evidently, the voice of uncertainty is still, is small, and not all species hear it.

We close this entry with outreach to other areas of comparative psychology that have important connections with our own.

First, this area has close ties to research on mirror self-recognition. The mirror paradigm devised by Gallup (1982) has had extraordinary influence, and promoted important debates, including whether animals other than primates have sophisticated forms of reflective mind, and whether primates other than apes do. The animal-metacognition studies in this context can be seen as complementary to those of Gallup.

They explore animals' cognitive self-awareness, whereas Gallup explored animals' bodily self-awareness. They also make a distinctive theoretical contribution, for showing robust cognitive self-awareness in monkey species, when those species have normally shown mirror self-recognition with great difficulty.

Second, this area raises crucial questions about what self-awareness is, and about how it is to be operationalized. There are dye-mark studies, metacognition studies, and so forth. The dye-mark studies can be questioned because low-level body-grooming utilities could underlie those phenomena. But the metacognition studies can be questioned as measures of self-awareness also, because the mental monitoring that monkeys show might not require the knowing of self, a feeling of selfness, and so forth.

Third, animal-metacognition research has close ties to work on self-control and agency. In Metcalfe and Son (2012), the highest level of auto-noetic metacognition was restricted to cases in which metacognition is imbued with self-awareness. For Metcalfe, this raised the question of whether animals understand the idea of their own agency within a task, and of whether they can report having or not having agency within a task as they perform it. Accordingly, researchers have begun to explore declarative reports of agency by humans. Metcalfe and her colleagues (Miele et al. 2011; Metcalfe et al. 2013) have used a video game in which mouse movements let one reach targets descending on the screen. By disrupting, fuzzing, or lagging the cursor control, one can reduce humans' effective agency in the task and they report this loss of agency sensitively. Couchman (2015) contributed perhaps the first comparative study of agency judgments across humans and monkeys. Humans and monkeys were trained to move a computer icon with a joystick while a distractor icon partially matched their movements. Both humans and monkeys were able to recognize and identify the icon that they were controlling. This suggests that they may have some understanding of self-agency. More research is certainly warranted on this facet of self-awareness and on its relation to metacognition.

Fourth, our research bears on animals' higher-level capacity for declarative memory and declarative cognition generally. In animal-cognition research, there has been a scourge of scare quotes surrounding constructs – traditionally forbidden in the behavioral zeitgeist – like “episodic memory,” “declarative memory,” “explicit cognition,” and so forth. However, many of the animal-metacognition paradigms have begun to show that animals are transcending the bounds of associative learning as it has traditionally been understood. Accordingly, it is sharply time to take all the scare quotes away, and use the sophisticated paradigms available now to explore animals' explicit and declarative cognitive capabilities systematically (Smith and Church 2017).

Fifth, the animal-metacognition literature seemingly presents paradigms that can bring comparative researchers close to the threshold of demonstrating animal consciousness. This idea extends back to Tolman (1927), who thought that animals' hesitating-vacillating behaviors at threshold could become “The Behaviorist's Definition of Consciousness.” This theme was expressed eloquently again when Weiskrantz (1986, 1997) presented a thought experiment in which animals were offered a commentary key so that they could express their mental states, a response beyond the responses devoted to the primary task. The metacognition paradigms are good instantiations of his thought experiment, and their metacognitive responses are good instantiations of his commentary key.

Indeed, in Cowey and Stoerig (1995), a kind of metacognitive response by blindsight monkeys essentially let them make declarations about their conscious awareness. The researchers gave monkeys a visual-detection task. When forced to answer, monkeys could successfully localize targets by pointing to their location, even within their impaired hemifield. This is consonant with the phenomena of blindsight. But Cowey and Stoerig also gave these monkeys a response that meant: The trial was Blank, or “I didn't see anything.” Remarkably, the animals used that response to comment on the trials presented in their impaired hemifields, even though they could answer those

trials correctly when required. They may well have been saying: “I didn’t see anything.”

Sixth, this literature on cognitive self-awareness presents an extraordinarily important bookend to the literature on other awareness (Theory of Mind) that explores whether animals know about the other minds in other bodies. The relation between self- and other-awareness has been an important topic in comparative theory. Humphrey (1976) made the famous proposal that metacognition arose to support social animals’ reading of the other minds around them. He called these mind readers Nature’s Psychologists. Carruthers (2009) took the stronger view that mind reading – the theory of the other’s mind – evolved first to serve social functions, and then only later was directed inward to ground metacognition.

The animal-metacognition literature makes important contributions to this ongoing theoretical discussion. For it is quite clear that in a variety of tasks monkeys show robust forms of cognitive self-awareness. Yet in many theory-of-mind tasks, monkeys display almost no capacity for showing other awareness. These findings, taken collectively, present a strong case that cognitive self-awareness has sometimes evolved on its own, not as a slave system to mind reading. Moreover, this evidence shows that cognitive self-awareness sometimes evolved first in the evolutionary progression. Given this evidence, perhaps we can understand why this evolutionary progression from self- to other awareness may even be mandatory and inevitable. If other-awareness evolved first, then one must assume that these creatures appreciated the mental states of others without appreciating their own. However, animals with no understanding of their own mind and mental state would have no basis for judging another’s mind and mental state. This would be like trying to judge what keys a conspecific has in its pocket, even though it has no conception of what keys and pockets are. Instead, if cognitive self-awareness evolved first, then the animal would understand mental states and mind, or keys and pockets. And then it would only be a small step to inferring that other animals have keys and pockets, too. This evolutionary progression seems more possible

and workable in preadaptation terms, and this evolutionary progression seems to be the one borne out by the animal-metacognition literature.

Seventh, broadening out, discussions like these encourage theorists to consider the overall factor structure of reflective mind in animals. Gallup (1982; see also Gallop and Suarez 1986) was very influential for his proposal that mirror awareness, self-awareness (metacognition), and consciousness all emerged together when, in some evolutionary transition to apes, all the facets of reflective mind began to shine brightly together. He took a g-factor approach to the emergence of reflective mind. However, it hasn’t been confirmed that this occurred. It is not clear whether reflective mind is all-or-none or unitary in Gallup’s sense. In fact, the animal-metacognition literature, especially regarding metacognition versus TOM, appears to speak against that possibility. No doubt these discussions will continue.

Eighth, the animal-metacognition literature has begun to make a constructive contribution to discussions about animal rights, and animal care/husbandry. The literature shows that many animals monitor their mental states, like uncertainty, confidence, and recollection. Therefore, it is perfectly plausible that they may monitor other aspects of their personal mental experience, including pain, discomfort, fear, and so forth. Thus, joining other research areas on high-level aspects of animal cognition, this literature systematically elevates comparative psychology’s view of animals’ reflective minds. It must also, therefore, elevate the level of care and respect that is owed to those animal minds and animal lives. For this reason, and for many other reasons, too, we are in the debt of many extraordinary research animals who have produced performances that have fostered profound theoretical development in this area, and who have been extraordinary ambassadors for their species.

### Synonyms

[Framing](#); [Simulative communication](#)

Metacommunication is a term developed by Gregory Bateson (1955/1972, 1956) to refer to signals that (intentionally or not) simulate other signals and, in obviously simulating, refer to those other signals for the signaler, the recipient, or both. Bateson conceived of some signals as natural indicators of some state, e.g., a baby's crying as an indicator of distress. If a baby simulated or re-created its cry when it was not upset (say, to play with making the sounds of crying or to get its caregiver to nurture it), the baby might emit the simulated cry in such a way that it was distinguishable (by the infant, by another, or by both) from a natural cry. Bateson viewed this evidence of the fact of simulation between the natural and simulated signals (i.e., this recognition of difference amid similarity or pretense) as itself a signal, communicating that the natural signal is being simulated. Critiques of Bateson's ideas argued that animals need not be aware of any simulation in play, and, indeed, many play behaviors are apparently not simulations (Mitchell 1990; Pellis 1988), though it seems likely that, e.g., some primates and canids are aware when they or others are simulating (see Mitchell 1991 for critiques and discussion). Almost identical ideas focusing on communicative simulations were developed apparently independently by Grice (1957) in his discussion of the development of Non-natural meaning (i.e., intending to communicate). Both authors viewed salient simulations as important in the evolution of human language, in that signals came to be used beyond their original ("natural") meaning and thus came to have a potentially dual meaning or function.

Although Bateson (1955/1972, 1956) viewed the term as applicable to a variety of simulations (including deception, imitation, pretense, threat: see elaboration in Mitchell 2002), he specifically singled out animal play as suggestive of metacommunication, as players simulate other activities, yet (apparently) recognize that these activities referred to in the simulations are not enacted, but instead playful versions are (e.g., when playfighting simulates fighting). Consequently, metacommunication in the animal literature has been almost exclusively used in discussions of play. In his elaboration of metacommunication, Bateson (1955/1972) developed the notion that implicit assumptions or signals that designate how to interpret messages are metacommunicative, calling these assumptions or signals "frames": "as in the case of the play frame, the frame is involved in the evaluation of the messages it contains, or the frame merely assists the thinker in understanding the contained messages by reminding the thinker that these messages are mutually relevant and the messages outside the frame may be ignored. In [this] sense... the frame is metacommunicative" (p. 188). In using Bateson's ideas to understand animal communication, Bekoff (1975) and others focused on metacommunication as framing, rather than as based on simulation (though such framing is only necessary if simulative metacommunication is not effective, i.e., if the simulation is not recognized as such). Metacommunication, in this view, was present when a signal that occurred prior to a behavior influenced the interpretation of that behavior. For example, a playface shown by a lunging primate just prior to the lunge allowed the lunger's play partner to expect play, rather than a fight. By this interpretation, metacommunication becomes indistinguishable from signaling. It is this use of the term "metacommunication" to refer to signaling in relation to other signals that remains prominent: e.g., even with simulative metacommunication present in "aggression-like elements" during play, authors take prior behavior that changes the meaning of subsequent behavior as evidence of metacommunication (Špinka et al. 2016). The playface is conceived to be necessary specifically because of the fact that the play

simulates fighting and might be misconstrued as fighting (although play faces are not always present during playfighting – Pellis and Pellis 1996). The playface is thus viewed as a natural signal of playful desire, much as crying is a natural signal of distress. Play signals themselves may be simulatively metacommunicative when they are used to signal play amid aggressive uses of playfighting (see Mitchell 1991; Pellis and Pellis 1996). Questions continue to arise as to whether play signals are natural (“emotive”), intentional (“cognitive,” “manipulative”), or both (Palagi et al. 2016; Pellis and Pellis 1996), suggesting that ideas about metacommunication in play still resonate with researchers unconcerned with Bateson’s formulations.

## Metamemory

Elizabeth Haseltine and Brielle James  
Georgia State University, Atlanta, GA, USA

## Synonyms

[Memory awareness](#)

## Definition

The awareness of one’s own memory system through the monitoring and control of memory strength for previously acquired events or information. This awareness results in the knowledge of what one does and does not remember.

## What Is Metamemory?

Memory systems allow individuals to store and retrieve information that is gained through their senses. Like many cognitive processes, memory is prone to error and can be inconsistent and undependable. This is shown during daily experiences such as going to the store or trying to remember work to-do lists, and even in cases of eyewitness testimony. Humans, and potentially other species, recognize and understand this truth and are able to compensate for some of the fallibility of memory by developing an understanding of their own personal memory systems. This capacity to be self-aware of one’s memory

processes is known as metamemory. Metamemory allows someone to recognize what they are cognizant of and recognize the limits of that knowledge. It is a system that enables one to monitor and consider the strength of their own memory and plays a crucial role in situations that involve strategy, planning, and performance evaluation.

The term “metamemory” was first coined by Flavell (1971) and was analyzed in depth a few years later (Flavell and Wellman 1977). It could broadly be described as “knowing about knowing” (Brown 1975). When detailed by Flavell and Wellman, metamemory was separated into two major components: sensitivity and variables. Today, the variables category can be referred to as declarative metacognitive knowledge, while sensitivity is generally associated with procedural metacognitive knowledge (Schneider 2001). Declarative knowledge describes the explicit awareness of how variables may impact one’s memory. In humans, this can be assessed through interviews and questionnaires. The procedural component of metamemory is the capacity to monitor and regulate memory and can be evaluated by asking participants to describe the process they used to complete a memory task (Schneider 2001).

Each of these two major divisions of metamemory may then be further subdivided. Declarative (variables) memory knowledge can be categorized into three subsections: person, task, and strategy (see Flavell and Wellman 1977). More relevant to animal research on metamemory, procedural (sensitivity) memory knowledge can be subdivided into two categories: monitoring and control. Monitoring allows one to make self-assessments during information acquisition and retrieval of memories. This enables greater comprehension about what has been retained and how reliable recall and recognition of the information may be (i.e., retrospective monitoring). Monitoring of memories further allows recognition of information that will need to be remembered as well as understanding the boundaries of one’s future recall performance (i.e., prospective monitoring). Prospective monitoring may appear in multiple forms such as ease-of-learning judgments, judgments of learning, and feeling-of-

knowing judgments (Nelson 2001). On the other hand, control enables the regulation of information at points of acquisition and retrieval to aid in processes such as planning, decision-making, and presenting relevant memory enhancing strategies. As in prospective monitoring, feeling-of-knowing judgments can play a role in control, allowing one to quickly make a decision about whether or not a piece of information is stored within one’s memory before memory monitoring initiates (Nelson 2001).

In humans, metamemory is not an ability present at birth. Like many cognitive capacities, metamemory develops with age through continual exploration and learning about the world. Research has shown that metamemory appears around the age of 4–5 years and continues to improve throughout the formative years (Lockl and Schneider 2006). Longitudinal studies on metamemory have produced interesting results, such as demonstrating a decline in older age as well as gender differences. Gender differences include women reporting greater levels of strategy use, memory efficacy, and control (Hertzog et al. 2019).

Procedural metamemory appears to have gained a larger focus over the years. Common studies on metamemory in humans include feeling-of-knowing judgments, tip-of-the-tongue phenomena, source-monitoring judgments, and confidence judgments (Schwartz 1994). As one may expect, all of these tasks rely heavily on the use of language. This greatly impacts the ability to test preverbal and nonverbal humans as well as nonhuman primates and other species. The language barrier has been a constant struggle within comparative studies; however, researchers working with nonhuman animals have designed numerous approaches to answer questions about metamemory. The following sections will summarize and describe a portion of this work on metamemory.

## Assessing Metamemory in Animals

The study of metacognitive processes in animals began when abilities of a bottlenose dolphin were

investigated (Smith et al. 1995). From this study, metacognitive capabilities and subsequently, metamemory research, took off. While limited by the inability to use language as a tool to assess the memory system in animals, researchers have found many creative ways to explore some of the same judgments of memory that have been studied in humans. Today, there is a large focus on pigeons (*Columba livia*; Inman and Shettleworth 1999; Roberts et al. 2009) and primates (Call 2010; Fujita 2009; Hampton 2001) in nonhuman metamemory research. Other species, such as rats (*Rattus norvegicus*; Templer et al. 2017) have also been tested for this ability, albeit not as extensively.

A significant number of animal studies assessing metamemory aim to observe judgments of knowing and uncertainty. Many such studies utilize delayed-matching-to-sample (DMTS) or categorization techniques. Typical matching-to-sample studies present a subject with a stimulus and the subject must then choose the image or item they were just shown out of an array of distractor stimuli. DMTS incorporates an additional element where the subjects must wait a predetermined length of time after initially seeing the target stimulus and before seeing the stimuli they must choose from. This delay in time encourages subjects to use their memory system and has helped researchers to judge levels of uncertainty in subjects by allowing them to either provide an answer to a DMTS trial for a desired reward or opt out of the trial for a lesser reward (Hampton 2001; Sutton and Shettleworth 2008). Further assessing certainty, researchers have also developed categorization tasks with the same element of allowing subjects to answer or opt out of trials (Adams and Santi 2011; Smith et al. 2009).

Other common tasks to assess metamemory include information-seeking tasks that enable subjects to fill their gap in knowledge or confirm an answer by searching for the solution before solving (Basile et al. 2009; Call and Carpenter 2001; Hampton et al. 2004). This type of study allows researchers to observe whether subjects recognize if they are unaware of the answer and that it is not stored within their memory. Evidence of metamemory in this task would appear as subjects

participating in a solution search when they are uncertain of the answer but foregoing this search in times when they are already aware of the answer. Results are indicative of one's faculty to use memory as a prompt to seek information.

## Metamemory in Apes

In one of the earlier tests of metamemory involving nonhuman species, Call and Carpenter (2001) tested 2.5-year-old children, chimpanzees (*Pan troglodytes*), and orangutans (*Pongo pygmaeus*) with an information-seeking task. The participants' goal was to locate a hidden food or sticker reward within one tube when presented an array of opaque tubes. In randomized trials, participants were able to see the tubes be baited or the baiting of the tubes was blocked by a barrier. Once baited, participants had the opportunity to look through the open ends of the opaque tubes in order to gain information about the contents of each tube. Overall, participants across species utilized efficient search strategies. In other words, when they observed the tubes get baited, participants tended to forego the search. However, during uncertain trials when baiting was blocked from view, participants were more likely to search the tubes.

In two independent studies, Suda-King (2008) and Suda-King et al. (2013) tested orangutans and gorillas (*Gorilla gorilla*) on object choice spatial memory tasks to observe decisions to opt out of responding during uncertainty. If individuals chose to decline a test, they would receive a guaranteed, but lower-valued food reward than if they chose to participate and gave a correct response. Researchers defined two criteria in their search for metamemory. First, subjects should have declined the test more often if the trial was considered to be difficult. Second, on trials where subjects may have chosen to decline the test (as opposed to forced trials), they should have shown higher accuracy in memory tests that they agreed to participate in. Supporting the first criterion, individuals of both species chose to not participate in more difficult memory tests during times when they were uncertain of the preferred reward location. Additionally, one individual

from each species satisfied the second criterion and performed significantly better during choice trials.

These promising results have not been without critique. Concerning uncertainty response tasks in which one may decline a test, Smith et al. (2009) believe subjects are able to recognize when it is effective to opt out by associating sets of stimuli in more difficult trials with the decline key, not because they can monitor their own mental state. In a critique of information-seeking tasks, Hampton et al. (2004) cited the generalized search hypothesis, stating that subjects may simply be searching for the reward until it has been located. In order to address these criticisms, Call (2010) utilized similar methods to the previously described Call and Carpenter (2001) study and tested all nonhuman great ape species (chimpanzees, bonobos (*Pan paniscus*), gorillas, and orangutans). In this three-experiment information-seeking task, researchers manipulated the information received (presenting auditory information via tube shaking or increased difficulty of visual searches with angled tubes), the interval between baiting the tube and choice selection to increase the potential of forgetting (and thus increasing uncertainty), and food quality (high versus low desired). As expected, auditory information and increased difficulty in visual search decreased information-seeking behaviors. Additionally, visual search increased when subjects were presented with higher stakes and with longer durations of time between baiting and retrieval. Results of this study further support the claims of metamemory and metacognitive abilities in apes.

Similarly, Beran et al. (2013) tested three enculturated chimpanzees in an information-seeking task. Utilizing the chimpanzee's training to name people, places, and items (including food) using pictorial symbols, the chimpanzees were tasked with naming food items placed in a container to receive the food as a reward. Critically, the subjects had the option to name the food immediately when asked or check the container where the food had been hidden before responding. When the food was made visible to the subjects, the chimpanzees were more likely to name the food item immediately without seeking any additional information. However, when the

food was not made visible to the subjects, they searched the container for the food item prior to naming it. Overall, the chimpanzee's information-seeking behavior suggested that they accurately remembered what they had or had not seen.

## Metamemory in Monkeys

Smith et al. (1998) had humans and rhesus macaques complete a serial probe recognition task in which they needed to decide whether a given stimulus had been or had not been in a serial list of two, four, or six images. As in previously described tasks (Suda-King 2008; Suda-King et al. 2013), the participants were given the opportunity to decline the presented test. Differing from the other studies, Smith et al. (1998) put a cost on their decline option in the form of time. For instance, the more an individual would decline a test, the longer the time delay would be before they would receive their reward. By giving the participants this punishment for using the option to opt out, the researchers assumed the chance to decline would be more sparse and more strategic. The results showed that the monkeys were sensitive to the fluctuating cost of the choice to decline. Additionally, they made more errors for stimuli in middle list positions, and this was also where they tended to decline taking the test most often. This suggested the monkeys recognized that they did not have a good memory for items in those list positions.

During a DMTS task, Hampton (2001) also allowed rhesus monkeys to opt out of completing the matching task. Here, the subjects would receive a lesser reward for declining a trial, as opposed to it resulting in punishment (Smith et al. 1998). Results showed that longer delays between the initial viewing of the target and the time when a matching choice needed to be made led to a decrease in accuracy and that the macaques chose to decline the tasks with longer periods of delay. Finally, high levels of accuracy were present when macaques chose to answer after long delays, compared to when they were forced to take the memory test. In combination with Smith et al.'s (1998) study, it appears that

macaques are sensitive to and can strategically utilize declining a test to optimize task outcome in both costly and beneficial scenarios. Overall, the shown pattern between decline responses and accuracy, combined with the increase of accuracy on chosen compared to forced trials, has been widely interpreted as a strong indicator of metamemory in nonhuman animals and the results have been held as a standard to indicate prevalence in other species as well.

Adapting the methods of Call and Carpenter's (2001) study with children and apes for rhesus macaques, Hampton et al. (2004) found similar abilities to those reported for the apes. When asked to locate a food reward between four opaque tubes, the rhesus macaques would strategically peer into the tubes when they were uncertain about the food's location (because they had not seen the baiting). In an impressive computerized study, Kornell et al. (2007) showcased both monitoring and control aspects of metamemory. Experiment 1 presented subjects with the chance to signal high or low certainty on various memory tasks, resulting in monkeys showing high-confidence on correct trials and low-confidence on incorrect trials. In Experiment 2, when given a sequence remembering task, macaques had to touch images in the order they were presented and could request hints at the cost of a food reward. Results showed that the subjects possessed control strategies and would request fewer hints when they could possess greater certainty. Together, these results indicated that rhesus macaques are able to differentiate what they know from what they do not know.

In another adaptation of Call and Carpenter's (2001) methods, researchers observed the tendency for capuchin monkeys (*Cebus apella*) to seek information (Basile et al. 2009). As before, the monkeys were given the chance to peek in opaque tubes and were tasked with picking the one containing a reward. Unlike young children, apes, and rhesus macaques, the capuchins did not increase their rate of information seeking when they did not see the experimenter bait the tube, signifying they are unaware of what they do not know. In another version of a DMTS task with a chance to opt out due to uncertainty, capuchin monkeys potentially showed some ability to

monitor memory trace strength (Fujita 2009). However, these results do not demonstrate strong evidence of metamemory as in apes and rhesus macaques. It is generally acknowledged that, to date, capuchins have not been able to show a solid representation of this ability. However, more research will need to be conducted to determine if this is a failure in task design or if there is a divide within primates and truly indicative of the absence of ability.

## Metamemory in Non-Primate Species

As in rhesus macaques, pigeon metamemory is highly studied, although the results are not nearly as conclusive. Some of the more prominent studies using pigeon subjects also involved DMTS tasks (Inman and Shettleworth 1999; Sutton and Shettleworth 2008). Inman and Shettleworth (1999) presented pigeons with a DMTS task that permitted subjects to gain six food pellets for the correct answer on a memory test or opt out of the memory test and choose a safe key, rewarding them with three pellets and the chance to bypass potential failure. The pigeons occasionally opted out of difficult trials; however, alternative interpretations could not be ruled out and the inconsistent results across individuals were deemed to be not indicative of metamemory.

Another DMTS task presenting pigeons with the chance to opt out of a problem came to a similar conclusion, as uncertainty responses that were made were not aligned with the strategies expected as a result of metamemory (Sutton and Shettleworth 2008). Combining methods conducted with primates, one study consisted of a computerized test that allowed pigeons to seek information before being given a DMTS task (Roberts et al. 2009). This four-part task asked whether pigeons would choose to "study" the target stimulus in a DMTS task by choosing an option indicating desired information or choose to move directly to the DMTS task without seeing the stimulus they would need to select after the delay to obtain a reward. Roberts et al. (2009) found the pigeons would continually forego seeing the target stimulus, which ultimately suggests the absence of metamemory.

Producing similarly weak results of metamemory, Adams and Santi (2011) trained pigeons on a duration matching-to-sample task to peck response buttons to classify short 2-s and longer 8-s light durations or indicate uncertainty and opt out of answering. During select trials, the pigeons would complete (or opt out of) memory tests after a retention interval (ranging from zero to 60 s) was inserted between the light duration and their classification task. This study further opposed the results found in rhesus macaques and overall, it appears no study thus far has supported this ability in pigeons. While it is easier to say pigeons don't possess the capability, like with capuchins, it is possible that this is a methodological failure to find an appropriate task to showcase the species' potential.

Studies with rats have expanded the possibilities of metamemory testing and its implications. Using uncertainty response experiments adapted for rats, researchers tasked their subjects with memory monitoring and observed the rats' responses when given the chance to opt out of a difficult task (Templer et al. 2017; Yuki and Okanoya 2017). Both studies offered subjects the choice to solve the presented problem for a greater reward or choose to decline answering, receiving a lesser reward while potentially signaling a diminished confidence in memory. Templer et al. (2017) tested subjects with a DMTS task while Yuki and Okanoya (2017) utilized delayed matching to position methods where subjects were required to remember a specific location and relocate it in a two- or six-choice task after a short time delay. Results from both experiments show that rats would participate in the tests they could have more confidence in and declined the memory tests where confidence would have been lower. However, in the case of the delayed matching to position task (Yuki and Okanoya 2017), these results were only seen in rats that completed the six-choice task. Rats given the two-choice task did not strategically use the possibility to decline tests.

In summary, there is varying strength of evidence for the potential capacity of metamemory in multiple species, including rhesus macaques, apes, and rats (Call 2010; Hampton 2001; Templer et al. 2017). Conversely, capuchin

monkey and pigeon studies have provided equivocal evidence indicating limited metamemory, if present at all (Fujita 2009; Roberts et al. 2009). The deficit of demonstrated metamemory in these two relatively intelligent species speaks to the complexity of metamemory. Overall, if the goal is to simply find evidence of metamemory processes that have developed in nonhuman animals independent of language, it does appear that there are positive results. Continued testing is needed to better understand the abilities within the animal kingdom, especially within the primate order, which shows mixed results between species. Further research may uncover a greater indication of capacity and whether these are legitimate species differences or task-specific.

## Controversies in Studying Metamemory in Animals

Across the various studies of metamemory, there is disagreement about the mechanisms behind this behavior in nonhuman animals. The longstanding debate is around whether positive results of metamemory should be explained by associative or cognitive principles (e.g., Crystal and Foote 2011; Hampton et al. 2004; Kornell et al. 2007; Smith et al. 2009). Some argue that reinforcement history (Crystal and Foote 2011) and memory trace strength of the primary representation (Adams and Santi 2011) are the mechanisms that should be attributed to metamemory behaviors. These associative explanations rely on a default response rule that selects for the behavior with the highest response strength. Sometimes this behavior appears metacognitive in nature (e.g., opting out of difficult trials), but does not posit the awareness necessary for metamemory. Crystal and Foote (2011) believed that researchers must be conservative and parsimonious when explaining the root of metamemory in nonhuman animals. According to Crystal and Foote, cognitive explanations are more complex than associative ones and, aligning with Occam's razor, cognitive explanations should be reserved until all associative principles have been eliminated as possible explanations. Like Crystal and Foote's position, hypotheses drawn from work done with pigeons

(e.g., Inman and Shettleworth 1999) also credits associative principles as the mechanism for metamemory behaviors in these nonhuman animals. They also put forth that memory trace strength acts as a discriminative stimulus (Inman and Shettleworth 1999), which allows pigeons to use a signal detection model to maximize rewards during metamemory tasks – an associative explanation of metamemory.

On the other hand, researchers such as Call (2010) and Smith et al. (2009) argue that metamemory (and metacognition more broadly) is a higher-order and controlled cognitive process. They view metamemory as a flexible decisional process in nonhuman animals (monkeys, apes, and a dolphin) and related to humans' reflective mind and consciousness (e.g., Smith et al. 2009). Other researchers (e.g., Basile et al. 2015; Hampton 2009) do not take such a hard stance in this debate and argue that metamemory in nonhuman animals is driven by multiple mechanisms to varying degrees. From their perspective, whether metamemory behavior derives from an associative or cognitive mechanism is less important than identifying the specific cues that support this behavior. They argue that the mechanisms for metacognitive behavior, including metamemory, can be both internal and external. Although, similar to Crystal and Foote (2011), internal cues should only be inferred once external stimulus control can be ruled out as the driving force for behavior (Hampton 2009). Hampton and colleagues (e.g., Basile et al. 2015; Hampton 2009; Templer et al. 2017) hold the position that both *public* cues and *private* cues may elicit metamemory behavior. Potential public cues prompting metamemory include response competition (including a generalized search strategy; e.g., Call 2010; Hampton et al. 2004), environmental cue associations, behavioral cue associations, and rote response learning, while private cues involve introspective monitoring of explicit memory or fluency effects (Basile et al. 2015). After ruling out various external sources of stimulus control, Basile et al. (2015) argued that metamemory in rhesus macaques can likely be attributed to an internal memory monitoring hypothesis. This hypothesis involves memory

strength serving as a discriminative cue for monkeys' metamemory behavior and is both associative (memory trace strength as a discriminative cue) and cognitive (monitoring of memory trace strength) in nature. Templer et al. (2017) suggested that metamemory in rats is also likely based on internal cueing from memory strength and not solely external stimulus control.

Kornell et al. (2007), however, took a different intermediary viewpoint of what the mechanisms of metamemory are. They do not support that metamemory behaviors can be explained simply by stimulus control, but also do not support metamemory as a conscious and self-reflective behavior in monkeys (or humans). Instead, they argue that metacognitive errors in memory tasks with monkeys result from unconscious inferences from task fluency while completing tasks.

## Conclusion and Implications

As described in the previous section, there are multiple contrasting opinions about the psychological mechanisms that best explain the presented results across a variety of species. Despite these differences, studies of metamemory in nonhuman animals have led to a variety of methods to test for this phenomenon in nonverbal ways. Continued metamemory research with nonhuman animals will help facilitate new methods to test explicit memory and the neural basis of metacognition in humans (Basile et al. 2015; Templer et al. 2017). These studies also provide a means to better understand the evolution and phylogenetic organization of metacognition. Further testing will determine if memory awareness is a widely distributed cognitive capacity among primates (i.e., human adults and children, apes, and monkeys) and its potential to have evolved multiple times through convergent evolution in other distant species (e.g., rats and dolphins; Hampton et al. 2004; Smith et al. 2009). Adaptively, metamemory would facilitate optimal foraging behaviors in these nonhuman animals, as just one example.

Studying metamemory in nonhuman animals also shines a light into the nature of animal minds

and intelligence. Given that metacognition is believed to be an aspect of self-awareness (Sutton and Shettleworth 2008), metamemory may broadly reflect animals' ability to understand their own and other's minds (Suda-King 2008). Additionally, studying metamemory from a comparative lens potentially provides information about nonhuman animals' consciousness, reflectiveness, and subjective experience (Basile et al. 2015; Smith et al. 2009). Overall, metamemory behaviors in nonhuman animals are functionally similar behaviors to the verbal, reflective processes in humans, and potentially the precursors of human metacognition and consciousness.

## Methylation

Akanksha Kushwaha  
Department of Zoology, Banaras Hindu  
University, Varanasi, India

### Definition

Methylation is defined as the addition of a methyl group to proteins and DNA by a group of enzymes called methyltransferases.

## Introduction

Methylation occurs both on DNA as well as on proteins. The reaction is catalyzed by group of enzymes known as methyltransferases. Methylation marks are reversible. Methyl marks are removed by another group of enzymes known as demethylases. Methylation is also involved in modification of heavy metals. Balance between level of methylation and demethylation regulates expression of genes, regulation of protein function, and processing of RNA. S-adenosylmethionine (SAM) acts as a donor of methyl group for addition by methyltransferases.

## DNA Methylation

DNA methylation is a process by which methyl groups are added to the DNA molecule. Methylation can change the activity of a DNA segment without changing the sequence. When located in a gene promoter, DNA methylation typically acts to repress gene transcription by preventing the binding of transcription factors either directly or through recruitment of methyl binding proteins and formation of repressor complex. DNA methylation takes place on those cytosine residues which are followed by guanine, generally known as CpG islands. It is catalyzed by DNMTs (DNA methyltransferases) that transfer methyl group from S-adenosylmethionine to cytosine residues. DNMTs are broadly categorized into de novo DNMTs and maintenance DNMTs. The de novo DNMTs, DNMT3a and DNMT3b, establish initial methylation patterns on previously unmethylated DNA, and the maintenance DNMT, DNMT1, establishes methylation patterns on hemimethylated replicating DNA. DNA methylation is an important regulator of various neuronal functions like memory formation and stabilization.

DNA methylation is also essential for normal development and is associated with a number of key processes including genomic imprinting, X chromosome inactivation, repression of transposable elements, aging, and carcinogenesis.

## Protein Methylation

Methylation of histones is widely studied among protein methylation. Methylation occurs at N-terminal tail of histone lysine and arginine and involves three different possible variations – mono-methylation, dimethylation, and trimethylation. These different forms of methylation influence chromatin structure differently and regulate expression either positively or negatively. Histone methylation is catalyzed by histone methyltransferases (HMTs) which add methyl group, while histone demethylases (HDMs) remove methyl group from specific arginine or lysine of histone H3 and H4. HMTs have a conserved SET (Suppressor of variegation, Enhancer of zeste, Trithorax) domain and are divided into seven families SUV39, SET1, SET2, EZ, RIZ, SMYD, and SUV4-20. This classification is based on the presence of different domains of protein along with the conserved SET domain. HDMs are divided into two classes: amine oxidase type lysine specific demethylases (LSD) and JumonjiC domain containing histone demethylases (JMJC). Histone methylation is implicated in memory and central nervous system (CNS) function. Methylation of histones can either increase or decrease transcription of genes, depending on which amino acids in the histones are methylated and how many methyl groups are attached. Methylation events that weaken chemical attractions between histone tails and DNA increase transcription by enabling the DNA to uncoil from nucleosomes due to which transcription factors, proteins, and RNA polymerase can access the DNA. This process is critical for the regulation of gene expression that allows different cells to express different genes.

## Michael Domjan

Mark A. Krause

Department of Psychology, Southern Oregon University, Ashland, OR, USA

## Biography

Michael Domjan is a prominent figure in the field of animal learning and comparative psychology, with major contributions spanning a 40-year period. Domjan's area of expertise is Pavlovian conditioning and its ecological and evolutionary bases. His empirical studies have focused primarily on conditioned taste aversion in rodents and conditioned sexual behavior in birds. His work is highly significant in that it bridges two areas of inquiry – animal learning and evolution – that have historically lacked empirical and theoretical synthesis. Furthermore, he has challenged many long-held assumptions about how humans and nonhumans learn.

Domjan was born in 1947 in Budapest, Hungary. In the aftermath of the Hungarian revolution in 1956, his family fled to Austria. After spending a year in Switzerland, the family settled in the United States with the help of a Rockefeller Foundation grant to his father, who was a prominent artist. Soon after arriving in New York, he and his brother were enrolled in the preparatory division of the Juilliard School of Music. However, his parents were concerned about him making a living as a musician and encouraged him to consider alternatives. He became fascinated with conditioning and learning at the Behavior Science Institute, a summer science program for high school students sponsored by the National Science

Foundation. Domjan spent the next five summers as a staff member of the Behavior Science Institute at Western Michigan University, working with Neil Kent and many of the pioneers of Applied Behavior Analysis. He also spent some time on the staff of the Fort Custer State Home, where Louise Kent had started an Applied Behavior Analysis program.

At the advice of Dr. Ron Hutchinson, Domjan entered the biopsychology doctoral program at McMaster University in 1969, where his focus turned to studies of Pavlovian conditioning. McMaster had a vibrant community of scholars working on issues of learning. Domjan worked in the laboratory of Shepard Siegel but was also heavily influenced by Bennett G. “Jeff” Galef and Herb Jenkins. Domjan began graduate school soon after Garcia’s groundbreaking discoveries of selective associations and long-delay taste aversion learning (Garcia and Koelling 1966), both of which were topics of extensive debate in the learning labs at McMaster.

### Early Work on Conditioned Taste Aversion

What made conditioned taste aversion (CTA) such a seemingly unusual phenomenon is that it did not conform to the characteristics of other types of conditioning. Conditioned taste aversion has unique features, such as its single-trial requirement and long CS-US delay. Another unique feature, identified by Domjan, was that, in CTA, the participant initiates contact with the CS (the flavored solution), rather than the CS being experimentally controlled and unavailable for direct interaction. Domjan speculated that the unique features of taste aversions could be due to this, instead of CTA being a specialized form of learning, as was proposed at the time. Domjan tested this hypothesis by developing experimental protocols that allowed him to present taste stimuli in the absence of active approach and ingestive responses. For example, Domjan and Wilson (1972a) found that rats that did not directly interact with the CS, due to paralysis

induced by curare injection, developed weaker aversions to saccharin paired with lithium than did rats that were not paralyzed. Domjan subsequently improved the technique of testing the role of ingestion in CTA by developing an oral infusion procedure using a cannula. Bypassing the process of ingestion using this technique resulted in reduced aversion conditioning to saccharin, as was found with the curare experiment (Domjan and Wilson 1972b). Domjan subsequently utilized the oral infusion technique to study numerous CTA related and Pavlovian phenomena. Among Domjan’s greatest early contributions was his discovery of the roles that ingestion-related physical sensations play in the acquisition of CTA. These ingestion-related experiences seem to act as “gating” mechanisms that bind sensory cues to eating and drinking.

Domjan’s important work on CTA coincided with growing interest among learning researchers into the functional and adaptive features of conditioning. Garcia and Koelling’s (1966) work on CTA complemented the work of Paul Rozin on specific hungers. Rozin suggested that the forms of learning that investigators were studying at the time constituted adaptive specializations (Rozin and Kalat 1971). Martin Seligman (1970) suggested a complementary notion of preparedness of learning. In many circles, the field of animal learning was shifting away from general process examinations of learning and toward more ecologically informed conceptualizations. However, in the decade that followed these claims, relatively little data emerged that could actually support these new perspectives (Domjan and Galef 1983). Domjan’s next research program on conditioned sexual behavior sought to address this deficit.

### Conditioned Sexual Behavior

Domjan accepted a tenure-track position at the University of Texas at Austin in 1973. In the middle 1980s, he shifted his focus to studying Pavlovian conditioning of sexual responses using Japanese quail (*Coturnix japonica*) as a

model species. Leaving CTA work did not mean leaving behind the major theoretical issues that he had been working on. In fact, studying conditioned sexual behavior, which had received very little attention to that point, was very much related to the topic of adaptive specializations of learning. The past 30 years of work in this area has brought the field much closer to making direct, causal links between conditioning and reproductive fitness.

*Coturnix* quail turned out to be an ideal species for these studies. The full range of copulatory behaviors readily occurred, and could be recorded, in the laboratory. When introduced to a female quail, males will approach (sometimes pursuing aggressively) until contacting her, often by grabbing her neck feathers with his beak. Receptive females squat and allow the male to mount her back, and, while using his outspread wings for balance, the male will contact his cloaca with that of the female and engage in a brief, stereotyped thrusting movement that culminates with delivery of sperm into the cloaca of the female. The unconditioned sexual stimuli and responses they elicit were readily measureable. Keeping with the same approach as his CTA work, Domjan developed a CS with which the birds could directly interact. In many of his experiments, Domjan and colleagues used a CS consisting of a foam pad covered with terry cloth that was roughly the size of a female quail body mounted on a small piece of plywood. Adjacent to the “body” of the CS model was an elongated “neck” made of the same material. This model could be paired with copulatory access to a female quail, typically for a 5-min period. A CS object consisting of the model just described, but with a taxidermically prepared head of a female quail attached to the neck piece, was used to examine how a CS object that included a naturalistic cue or “sign stimulus,” and could support the full range of sexual behavior, influenced conditioning relative to a CS object that lacked any naturalistic features.

Falih Köksal, who was working in Domjan’s lab while on sabbatical from his position at Bogaziçi University in Istanbul, tested whether

the naturalistic CS would resist the blocking effect. The blocking effect is a highly repeatable, standard phenomenon observed in laboratory studies of learning in which conditioning to a CS is attenuated if a different CS that was previously paired with the same US is also present during conditioning. However, Köksal and Domjan found that the naturalistic CS was highly resistant to the blocking effect: Male quail showed strong conditioned responses toward it even when encountering it along with a previously conditioned arbitrary CS. This was a highly unusual finding. The blocking effect had been demonstrated in countless laboratory experiments using stimuli such as audio or visual cues: It was regarded as a well-established general learning process. So too were the phenomena of extinction, habituation, and attenuation of responding with second-order conditioning and other processes. However, results from studies that implemented the naturalistic CS often ran counter to general process learning theory predictions (reviewed in Domjan et al. 2004; see also Domjan et al. 2000). It would seem that Pavlovian conditioning of sexual behavior occurs in relation to its ecological relevance. That is, it is adaptively specialized. Ecological relevance also plays a role in fear and appetitive conditioning (Domjan and Krause 2017).

A widely cited and influential review by Domjan (2005) examined the functional utility of Pavlovian conditioning. Specifically, this work discusses how, in natural circumstances, CSs have a preexisting relation to the US, and, importantly, learning about responding to the biologically significant US is of greater evolutionary importance than is responding to the CS. Domjan (2005) applied this notion to numerous conditioning phenomena including lactation, poison-avoidance learning, drug tolerance, and eyeblink, sexual, and fear conditioning. These examples demonstrate the adaptive significance of Pavlovian conditioning without requiring a creative story to explain how the results make biological sense. The results make biological sense because the learning itself occurs in a biologically relevant context to begin with, and the learning directly

modifies how organisms interact with biologically relevant stimuli. Even more direct evidence for the adaptive significance of Pavlovian conditioning was demonstrated by Domjan and colleagues in numerous experiments showing that quail exposed to a Pavlovian cue prior to mating opportunities has fertility advantages over unsignaled animals (Domjan et al. 2012).

## Other Contributions and New Directions

In addition to his numerous research achievements, Domjan has generously served his university and professional psychological organizations. He was the psychology department chair (1999–2005) and the founding director of the Imaging Research Center at the University of Texas (2005–2008). He served as president of APA division 6 (Behavioral Neuroscience and Comparative Psychology) from 1999 to 2000, was president of the Pavlovian Society of North America (2006–2007), and was editor for the *Journal of Experimental Psychology: Animal Behavior Processes* (1986–1991). Domjan was also co-director of the NIMH training program in Neurobiology and Behavior at the University of Texas (1993–2003). Domjan's dedication to education and teaching throughout his career is evident from his authoring two widely adopted textbooks on conditioning and learning. His primary textbook, *The Principles of Learning and Behavior*, has been a staple of the field since 1982 and is now in its seventh edition (c 2015). His book *The Essentials of Conditioning and Learning* has been translated into Spanish, Turkish, and Arabic and is now in its fourth edition (c 2018).

In recent years, Domjan has rekindled his interest in music. After a 35-year hiatus, he went back to playing his Tertis viola and started teaching an undergraduate seminar in music and psychology. He also initiated the Tertis/Pavlov Project in which he explores connections between music and psychology through a series of instructional videos that are available on YouTube. These videos include titles such as “How is Pavlovian

conditioning relevant to music” and “What I learned in a music conservatory that made me a better scientist.”

## Michael J. Beran

Michael J. Beran

Department of Psychology, Language Research Center, Georgia State University, Atlanta, GA, USA

### Early Life and Educational Background

Beran was born to Ellen L. and Robert A. Beran on August 11, 1973, in Middlefield, OH, but he grew up in Birmingham, AL, with one brother, Matthew. He received his B.A. in Psychology from Oglethorpe University in 1995, after some time as an accounting major, a business major, and a political science major (as well as at least one semester where he was undeclared!). Apparently what was required was the time needed to take courses in cognitive psychology and animal learning, and the realization that people could study both. He discovered this and his broader enjoyment of psychology because of the guidance of three faculty members, Nancy Kerr, Timothy Hand, and Adrian Brock. He received his M.A. (1997) and Ph.D. (2002) in the Department of Psychology at Georgia State University. His dissertation research focused on mathematical operations by chimpanzees and was conducted under the supervision of David A. Washburn, who he also routinely defeated at racquetball, basketball, and ping-pong, or at least that is how he remembers things. Additional mentors during his graduate career were Duane Rumbaugh and James Pate, and he is grateful to these three people for all they have done for him. He tries every day to pay that forward through work with his own students and other students who he works with. In his career, he is most proud of who those students have become.

### Professional Career

Beran took a research staff position at Georgia State University during the latter part of his graduate training, with support from NICHD and

support as the inaugural Duane M. Rumbaugh Fellow at Georgia State. He has remained at Georgia State University throughout his career, although he also spent time as a Visiting Lecturer at Spelman College from 2003 to 2007. He was a Research Associate and then Senior Research Associate at the Language Research Center of Georgia State before joining the Psychology Department at GSU as Associate Professor in 2015. He has authored more than 250 publications during his career including more than 150 peer-reviewed journal articles, which have appeared in outlets such as *Proceedings of the National Academy of Sciences*, *Psychological Science*, *Current Directions in Psychological Science*, *Current Biology*, *Journal of Experimental Psychology: General*, *Journal of Experimental Psychology: Animal Behavior Processes*, *Journal of Comparative Psychology*, *Animal Cognition*, and *Animal Behaviour*.

Beran has received several awards and recognitions. He is a Fellow of the American Psychological Association (APA Division 3 and Division 6) and the Psychonomics Society. He served as the President of the Southern Society of Philosophy and Psychology (SSPP), as well as serving as the Treasurer of that organization. He has served on the Executive Councils of the Southeastern Psychological Association and Division 3 and Division 6 of the APA, and he has been elected as President of the Southeastern Psychological Association. He received the Brenda A. Milner Award from the APA and the Richard M. Griffith Memorial Award from the SSPP.

Beran serves as the current co-editor of *Animal Behavior and Cognition* and is on the editorial boards of *Cognition*, *Frontiers in Comparative Psychology*, *Journal of Comparative Psychology*, *Comparative Cognition & Behavior Reviews*, *Learning & Behavior*, *Journal of Experimental Psychology: Animal Learning and Cognition*, *Animal Cognition*, and the *International Journal of Comparative Psychology*. His research has been supported by grants from the National Science Foundation, the National Institute of Child Health and Human Development, the European Science Foundation, and the Templeton Foundation.

## Research Interests

Beran and his students and collaborators focus on comparative cognition with an emphasis on nonhuman primates, particularly chimpanzees, capuchin monkeys, and rhesus monkeys, and human children and adults (Beran 2015; Beran and Heimbauer 2015; Beran et al. 2015a, 2016; Heimbauer, Beran, and Owren 2011). They sometimes work with other species, such as elephants, bears, gorillas, and orangutans.

Beran has assessed counting and arithmetic skills in nonhuman primates, human adults, and human children. His research has contributed to the notion that other species share with human an Approximate Number System (ANS), in which quantitative information including the numbers of items in sets can be encoded and represented, but with a degree of increasing inexactness as a function of true size, amount, or number (e.g., Beran 2001, 2007; Beran and Beran 2004; Beran and Parrish 2016). Among the many things that chimpanzees and monkeys have shown is that they can learn the values of Arabic numerals. They also can compare sets of items on the basis of numerosity, even when items are presented one at a time and the whole set can never be seen at once, and even when they have to compare auditory sets (hearing dropped items) compared to static visual sets (seeing all items at once). Sometimes, however, they show perceptual illusions about size similar to those seen in humans (Parrish and Beran 2014).

Beran also has made contributions to the study of metacognition in nonhuman animals (Beran, Brandl, Perner, and Proust 2012). Here, the question is whether animals may experience some sense of knowing what they do or do not know when faced with a decision. This is a difficult thing to assess in animals given the role of verbal reports in our understanding of human metacognition. However, certain experimental procedures have provided insights into the metacognitive skills of nonhuman animals (e.g., Beran and Smith 2011). For example, monkeys can be presented with various psychophysical and memory tasks for which stimuli can be categorized objectively as more difficult or less difficult for the animals based on task

performance. Animals also are given an additional response option, called the uncertainty response, that allows the animals to “escape” from choices that are too difficult or error-risking. In many cases, the animals use that response on exactly those trials for which the primary response is made least efficiently. This suggests that animals may monitor their own knowledge states when faced with decisions about how to respond to stimuli. Beran has focused particularly on chimpanzee metacognition (e.g., Beran, Smith, and Perdue 2013), demonstrating that these animals seek information based on what they know (or do not know), and they also provide measures of confidence in their own memory abilities. They do this by anticipating food reward for correct responses even before any external feedback is given to them – in essence by responding as if they know they are going to be correct or are not sure about that (Beran et al. 2015b).

Beran has studied future-oriented cognitive processes in animals and children. The ability to flexibly plan for the future has long been reserved for humans, and some have argued that animals are “stuck in time,” and they cannot think about the past or future because their behavior is affected only by their current needs and surroundings. However, animals may show capacities for mental time travel. Beran and his students and colleagues test nonhuman primates’ ability to anticipate future situations and plan future actions so as to determine continuities and discontinuities in the prospective memory and planning abilities of humans and other primates. This research has shown that nonhuman animals do have prospective memories and can anticipate future needs and remember to make responses in the future (e.g., Beran, Evans, Klein, Einstein 2012).

Beran also has spent his career learning about how nonhuman primates demonstrate self-control by delaying gratification. Delay of gratification occurs when one chooses to wait for something bigger or better rather than taking something that is available more immediately. Beran devised a way to use with nonhuman primates a task originally presented to children. In this task, animals learn that food items continue to pile up before them as long as they do not eat any. Thus, the

longer they wait, the more they get by delaying gratification. This simple technique has provided compelling evidence that chimpanzees show excellent delay of gratification (sometimes for periods in excess of 20 minutes with highly preferred food accumulating in front of them). Even rhesus monkeys and capuchin monkeys, traditionally viewed as more impulsive species, show some success with this task. Beran and his colleagues also have shown that chimpanzees can even use self-distraction to help aid delay of gratification (Evans and Beran 2007).

Ultimately, the “lab culture” that Beran tries to instill in these and other research programs is inspired by this quote from Edward Tolman in 1959 – “Since all the sciences, and especially psychology, are still immersed in such tremendous realms of the uncertain and the unknown, the best that any individual scientist, especially any psychologist, can do seems to be to follow his own gleam and his own bent, however inadequate they may be. In fact, I suppose that actually this is what we all do. In the end, the only sure criterion is to have fun.”

## Michael Tomasello

Patricia J. Brooks<sup>1</sup> and Jeremy Sawyer<sup>2</sup>

<sup>1</sup>Department of Psychology, College of Staten Island and the Graduate Center, CUNY, Staten Island, NY, USA

<sup>2</sup>Department of Psychology, The Graduate Center, CUNY, New York, NY, USA

## Introduction

Michael Tomasello (b. 1950) is an American psychologist known for his ground-breaking experimental studies of communicative development, cultural learning, and cooperation in humans and nonhuman primates. Since 2016, he has been Professor of Psychology and Neuroscience at Duke University. Tomasello's program of research has focused on the social-cognitive origins of uniquely human abilities and cultural inventions, such as language, complex tool use, advanced technologies, and social institutions. Several key themes have been emphasized. First, human language and gestural communication are acquired in contexts of social interaction and shared attention. Within these contexts of joint engagement, children are aware of their partner(s) and what they are doing together and can make sensible inferences about what their partner has in mind when communicating via speech or gesture. This ability to infer their partner's communicative intentions allows children to work out the meanings of words and their complex patterns of usage. As such, language development relies on children's use of sophisticated social-cognitive abilities rather than an innate knowledge of grammar.

Second, humans are experts in cultural learning and collaborative activity. Young children

grasp that interactions with their caregivers are generally cooperative, and they are motivated to help or play along. Children quickly come to understand that human social conventions, such as games and table manners, follow rules that are mutually agreed upon, and they are interested in learning to do things in culturally appropriate ways. Tomasello has contrasted children's apparent motivation to cooperate, share attention and mental states, and enforce socially established rules and moral codes with the more independent, problem-solving orientations of nonhuman primates, such as chimpanzees and orangutans. He has argued that human social interactions differ from those of other animals in that they are based on "shared intentionality," which includes the motivation to mutually understand conspecifics and share collaborative goals (Tomasello et al. 2005). Such collective, shared aims allow humans to work together on a daily basis in myriad ways, large and small, and provide the foundations for human culture and social institutions.

Tomasello's research contributions have been honored with numerous awards and prizes, including the Fyssen Foundation Prize for Cognitive Science (2004), Sir Frederic Bartlett Prize and Lectureship (2009), Heineken Prize for Cognitive Science (2010), Wiley Prize in Psychology for Lifetime Achievement from The British Academy (2011), and the Distinguished Scientific Contribution Award from the American Psychological Association (2015). Tomasello received the William James Book Award from the American Psychological Association for *The Cultural Origins of Human Cognition* (Tomasello 1999), the Cognitive Development Society Book Award for *Constructing a Language: A Usage-Based Theory of Language Acquisition* (Tomasello 2003a), and the Eleanor Maccoby Book Award from the American Psychological Association for *Origins of Human Communication* (Tomasello 2008). He received the Jean Nicod Prize for Philosophy of Cognitive Science (2006) with his lectures published with commentaries in a volume titled *Why We Cooperate* (Tomasello 2009).

## Biography

Tomasello obtained his Bachelor of Arts degree in Psychology from Duke University in 1972 and his Ph.D. in experimental psychology from the University of Georgia in 1980. His dissertation, conducted under the supervision of Ernst von Glasersfeld, was a diary study of his daughter's acquisition of verbs, later published as a monograph titled *First Verbs: A Case Study of Early Grammatical Development* (Tomasello 1992). In this monograph, Tomasello proposed the “verb island” hypothesis, which posits that grammatical development hinges on children's initial acquisition of individual verbs. As their vocabularies develop, young children begin to notice recurrent grammatical constructions associated with semantically related verbs, which they gradually redescribe in the form of more abstract rules and categories. Tomasello's proposal that grammatical knowledge is acquired in an item-by-item, piecemeal fashion from verbal input was a direct challenge to the nativist proposal, endorsed by Noam Chomsky and Steven Pinker among others, that an innate Universal Grammar (UG) underlies all human languages. In lieu of UG, Tomasello highlighted other cognitive abilities crucial for language learning, such as children's ability to partition complex events into constituent parts for word-to-world mapping. Tomasello emphasized children's ability to link expressions together, insert nouns into slots in verb argument structures, and draw analogies between words with similar combinatorial properties as providing the basis for linguistic generativity. In developing his Usage-based Theory of Language Acquisition, Tomasello borrowed ideas from cognitively oriented linguists, such as Ronald Langacker and Adele Goldberg, whose views he promoted in a series of edited volumes (Tomasello 1998, 2003b).

Upon completion of his doctoral studies in 1980, Tomasello joined the faculty of Emory University, where he remained until 1998. While at Emory, Tomasello initiated a series of studies exploring the social bases of communicative development, with a focus on joint attention,

imitation, and gesturing as precursors to language. Tomasello's socio-cultural framework was influenced by Jerome Bruner and Lev Vygotsky, who emphasized the social and cultural context of communicative development and viewed caregivers as providing a support system that scaffolded language acquisition. Under this view, children participate with others in routinized activities, such as reading picture books, which provide predictable formats for identifying the referents of words. In such contexts of joint engagement, children share their interests with others, while caregivers offer linguistic descriptions of direct relevance to what the child sees and has in mind. Over time, the dynamic of joint engagement shifts: young infants are supported by caregivers who “follow into” their activities (e.g., commenting on what the child is looking at), whereas at older ages children can effectively initiate bouts of joint engagement by proactively using gestures like pointing and showing, as well as vocalization, to share attention (Carpenter et al. 1998). Tomasello's studies highlighted how young children come to view others as intentional agents who engage in purposeful communication and how children gradually co-opt the communicative devices used by others for their own communicative purposes. For Tomasello, the child's ability to infer the intentions of others is the cornerstone of successful joint action and knowledge transmission and is an early manifestation of their tendency to view routine social interactions as inherently cooperative.

While at Emory, Tomasello became affiliated with the Yerkes Primate Research Center and began conducting comparative research on tool use, learning via imitation, gestural communication, and theory of mind in young children and apes, culminating in the volume *Primate Cognition* (Tomasello and Call 1997). Tomasello's observations of cross-species differences in the social transmission of knowledge led to the hypothesis that uniquely powerful forms of cultural learning in humans serve as a ratchet to prevent slippage of technological knowledge and accumulated wisdom over human history. Thus, according to Tomasello's “ratchet effect,” each

new generation assimilates the collective cultural wisdom and cultural tools developed by previous generations (Tomasello et al. 1993). These collectively created cultural settings and artifacts then form the milieu in which succeeding generations further develop their cognitive capacities through social learning in cooperative activities. In studies of tool use and gestural communication, Tomasello highlighted the ways in which non-human primates' problem-solving methods are akin to trial-and-error, with less attention or interest in the specifics of *how* someone else has solved the problem. Human children, in contrast, are especially interested in the means to the end, as evidenced by their propensity to "over-imitate" by including irrelevant actions in their efforts to perform tasks exactly as adults have modeled them (cf. Whiten et al. 2009).

Tomasello moved to Leipzig Germany in 1998, where he served as Co-Director of the Max Planck Institute for Evolutionary Anthropology and Co-Director of the Wolfgang Köhler Primate Center (appointment ending in 2018). Around this time, Tomasello began a new line of research on the social-cognitive abilities of dogs (e.g., Hare et al. 2002), advancing the "Social Dog, Causal Ape" Hypothesis that dogs have enhanced skills in reading humans' social and communicative behaviors (e.g., using human pointing to help locate hidden food) relative to apes. Tomasello posited that during the domestication process humans exerted selection for social communication skills in companion dogs, whereas in the absence of domestication, apes developed adaptations for individual foraging, which were more focused on physical causation than social-communicative processes.

Over time, Tomasello's research program shifted its focus from language acquisition toward greater emphasis on cooperation and collaborative activity as the foundation of human cognitive and cultural development. Tomasello illustrated the human propensity towards cooperativeness with findings that infants spontaneously offer altruistic help to adults who, for example, drop a book or need help opening a door (Warneken and Tomasello 2006). Nonhuman primates, in contrast, engage in rudimentary forms of cooperation,

yet rarely demonstrate altruistic resource sharing. In addition, during cooperative activities, when a partner stops collaborating (as an experimental manipulation), human toddlers make communicative attempts to reengage the partner in the shared goal, while chimpanzees do not, suggesting that a unique human form of shared intentionality is already evident in the second year of life.

In addressing the question of what separates human and animal cognition, Tomasello pitted the "general intelligence" hypothesis, which proposes that humans developed superior general cognitive functioning across all domains, against the "cultural intelligence" hypothesis, which argues that humans have species-specific social-cognitive skills that enable groups to invent cultural tools, symbols, and social practices. In comparing human toddlers with apes (chimpanzees and orangutans), Tomasello and colleagues observed similarities across species in cognitive skills for analyzing the physical world, but superior skills among children in cognizing the social world (e.g., social learning, communication, and theory of mind), which supported the "cultural intelligence" hypothesis (Herrmann et al. 2007).

Frans de Waal and others (2008) have questioned the "cultural intelligence" hypothesis, citing studies suggesting that nonhuman primates have greater cultural learning skills than apparent in Tomasello's research. In addressing this debate, Tomasello has never denied that nonhuman primates engage in social learning, while maintaining his argument that humans have evolved qualitatively more powerful forms of cultural intelligence and social learning that "bootstrap" the development of other cognitive capacities, such as language, from a young age. In recent years, Tomasello has acknowledged that non-human primates can exercise formidable theory of mind and intention reading. In considering human uniqueness, Tomasello argues that apes engage their social cognition in a competitive social milieu, reading the intentions and assessing the knowledge of other primates in order to better compete with them for limited resources such as food. Humans, in contrast, are an "ultra-social animal," far more adept than apes at developing shared goals and working toward them collaboratively.

## Conclusion

Working at the intersection of child development, cultural-historical development, and human evolution, Tomasello has made extensive and innovative use of comparative experimental methods to advance his hypothesis that powerful forms of social cognition distinguish humans from other species. His work emphasizes shared intentionality, defined as the ability and motivation to establish mutual understanding and shared goals in cooperative activities, as the critical factor underlying successful transmission of complex forms of knowledge, such as human language, over generations with sufficient stability to support cumulative cultural advancement.

## Why Do We Need a Microarray?

Biological systems are one of the most complex systems known to mankind. Thousands of gene and protein expressions change in tandem in

response to external and internal stimuli. For a biologist to be able to track all these changes simultaneously is no small task. Conventional techniques to track one gene or protein at a time are inefficient at best.

There is need for techniques that can track thousands of genes or proteins simultaneously. Time-efficient high throughput techniques are the need of the hour. Microarray is one technique that serves the purpose.

## What Is a Microarray?

A microarray refers to a technology in which “probes” (which detect “targets”) are arranged on a solid surface in the form of a two-dimensional array (Bumgarner 2013). Such an arrangement of multiple probes coupled with suitable detection method allows high throughput, multiplexed, parallel processing of samples to enable the researcher to detect changes in multiple analytes at the same time.

## How Does a Microarray Work?

The heart of the functionality of a microarray lies in its arrayed assembly. Multiple probes are arranged in the array in a position-specific manner so that exact location of each probe is known. Samples containing targets are labeled with a suitable detection reagent, like a fluorophore. When labeled samples are added to the array, probes would bind to their respective targets, in a specific manner. This arrayed assembly and specific binding is what makes a microarray “work” (Primrose and Twyman 2010).

Thus, the specifically bound target gets immobilized and the intensity of its fluorescent label indicates the abundance of that target. If more amount of a target is present in the sample, it would be bound and immobilized to a greater extent and would give a higher fluorescence reading. As the position of each probe in the array is known, the fluorescence coming from a certain position can be attributed to that particular probe and its specifically bound labeled target.

Probe and target depends on the type of microarray. DNA microarray is the most common. In a DNA microarray, short nucleotide sequences serve as the immobilized probe. Target comprises of labeled cDNA or genomic DNA or RNA depending on the application (Brown 2010). In protein microarray, capture proteins (including antibodies), ligands, or antigens form the immobilized probe while labeled proteins or small molecules form the target.

## History of Microarray

The idea of microarray was born with the development of antibody microarrays by Tse Wen Chang in 1983. This provided the base for the initial framework and concept of microarrays. Advancement continued at a slow pace till 1995, when Ron Davis and Pat Brown of Stanford University published a path-breaking paper in Science entitled “Quantitative Monitoring of Gene Expression Patterns with a Complementary DNA Microarray” (Schena et al. 1995). This gave impetus to the industry to develop “gene chips,” a fancy name for microarrays. Later, the microarray industry flourished with establishment of big-money companies and made innovative additions to the repertoire of microarray formats.

## Types of Microarray

There are different types of microarrays available in the market. DNA microarray, protein microarray, reverse phase protein microarray, carbohydrate microarray, antibody microarray, and transfection microarray are some of the well-known microarray types (Wilson and Walker 2005). Irrespective of the type, the underlying principle remains the same. The difference lies in the choice of probes and targets.

## Model Workflow of a Microarray Experiment:

The following workflow is a typical example of how a microarray experiment is executed. This example deals with gene expression profiling

using a DNA microarray, which is one of the most common uses of the microarray technique.

1. mRNAs are extracted and purified from control and treated samples.
2. mRNAs are reverse transcribed to cDNA (complimentary DNA).
3. cDNAs are labeled with detectable tags like a fluorophore. For single channel detection, all samples are labeled with the same fluorophore. For two-channel detection, distinguishable tags are necessary.
4. Labeled cDNAs are loaded on to the microarray chip to allow them to hybridize to corresponding probes.
5. Unbound and nonspecifically bound targets are washed off.
6. Bound cDNAs(targets) are detected using a laser scanning system.
7. Acquired data is normalized against reference standards and then analyzed to find out fold up-regulation or down-regulation in gene expressions.

### One-Channel Versus Two-Channel Detection

In the one-channel method, all the samples are labeled with the same tag. Only one sample is hybridized and detected at a time. Comparison is made between two samples that are detected separately.

In the two-channel method, samples to be compared are labeled with distinguishable tags. Two samples having dissimilar tags are mixed and simultaneously hybridized to the chip (which contains the arrayed probes). Abundance of both the tags (representing the two samples) is measured at the same time. Ratio of the signal from the two tags tells us about the relative changes in target expression between the samples.

Single-channel detection method suffers from batch variation and saturation effect. Samples are detected separately and the experimental condition for different samples may not be exactly identical. Thus comparing data from separate hybridization experiment may lead to erroneous

findings. In two-channel system, samples to be compared are used in a single experimental set up and hence can overcome this drawback.

Probes can also get saturated by targets in such a way that the difference in expression levels of targets goes unnoticed. Any difference in expression levels beyond the saturation level of probes would go undetected. In two-channel system, the ratio of the two tags provides information about the relative changes in gene expression and hence, there is no such issue.

One limitation of the two-channel system lies in the number of experiments needed to be performed. For comparing  $i$  number of samples, the number of experiments to be performed is  $i(i - 1)/2$ .

This means that two-channel system is not feasible if a large number of samples are to be compared, unless a reference sample is present (in which case number of experiments to be performed is  $i - 1$ ). One-channel system is the only option in such cases.

Accuracy of two-channel system may suffer due to difference in labeling efficiency between two fluorescent tags. One tag may label more efficiently than the other, leading to over-estimation of targets in that sample. One-channel system does not suffer from this limitation.

Moreover, in one-channel system, a single aberrant sample cannot affect the raw data derived from other samples, because each array chip is exposed to only one sample. In two-channel system, single aberrant data may obscure raw data of the second sample.

### Applications of Microarray

The basic principle of microarray has been expanded to put it to use for a multitude of purposes. By choosing appropriate probes and targets, a wide range of applications has been made possible.

- Gene expression profiling allows the researcher to find out relative changes in mRNA expression levels between samples.

Small nucleotide sequences are used as probes and cDNA derived from mRNA are used as targets.

- Comparative genome hybridization helps in analyzing copy number variations (CNVs) and genome content of patient samples or between closely related organisms.
- Single nucleotide polymorphisms can be detected by using probes that are specific to different variant forms of a gene. Such mutant forms may have implication in predisposition to diseases, drug response, and other physiological factors, and their detection can help in providing better medical care.
- ChIP-on-chip allows one to find out the genome-wide binding sites of transcription factors and DNA-binding proteins.
- Alternative spliced forms of genes may be detected using probes specific to exon junctions or individual exons. Fusion genes can also be detected using probes specific for chimeric transcript junction. Fusion gene detection is important in several cancers, such as BCR-ABL fusion gene.
- Protein microarray may help in discovery of novel biomarkers associated with certain conditions. Protein expression profile under different conditions may be explored. Protein-protein interactions, protein-ligand interactions can also be studied. Another important application of protein microarray is in detection of posttranslational modifications like phosphorylation, acetylation, and others.
- Reverse phase protein microarray uses immobilized cell lysates as the target and labeled antibodies serve as the probe. Cell lysates from different biological samples are arrayed on the chip, and antibody is used to probe and compare the abundance of any specific protein between the arrayed cell lysates.
- Peptide microarray uses short peptides as probes to pinpoint the position of epitopes or discovering key residues involved in protein-protein binding.

### Alternate Formats

Apart from the standard chip-based formats, bead-based microarrays are also available. Each bead contains a specific probe and is distinguishable by its unique ratio of two or more dyes that allows it to produce a characteristic and distinct color signature.

### Synthesis of Microarrays

Fabrication of microarrays can be done by a variety of methods. For DNA microarrays, there are two approaches. In spotted microarrays, the probes are presynthesized and then spotted on to the chip surface using robots. Alternatively, in situ manufacturing process is employed in which the oligonucleotide probes are directly synthesized on the chip.

### Future of Microarray

Microarray faces tough competition from RNA-Sequencing and mass spectrometry-based quantitative proteomic techniques. Microarray has a few significant limitations:

1. It is an indirect measure of the target abundance.
2. Signal is linearly proportional to the abundance only over a limited range.
3. It can only detect targets for which probes are available.
4. Mismatches are likely for sequences with high sequence homology or highly variable genomes. Different genes having high sequence homology may bind to the same probe. In genomes with high degree of variability, the designed probe may not be able to bind to its target due to sequence variation between the reference target and actual target.

All these factors make direct detection of target abundance a more sensible choice. RNA-Sequencing is able to directly read the nucleotide bases. Mass spectrometry-based quantitative

proteomic techniques allow simultaneous comparison of up to 10 samples.

With alternative techniques becoming more and more economical, microarray usage is bound to witness a slowdown. But still, microarray provides simplicity, versatility, customizability, and economy that are yet unparalleled. In all likelihood, microarray will still have its own niche usage and continue to be an important technique at the disposal of a researcher.

## Definition

Cognitive abilities of laryngeal echolocating bats viewed through perception, learning, and memory.

## Introduction

Echolocating bats have been traditionally classified in the suborder Microchiroptera (microbats) within the order Chiroptera, although this classification has been recently modified on the basis of new molecular findings (Teeling et al. 2005). There are over 1000 species of echolocating bats including the sac-winged bats, the mouse-tailed bats, the horseshoe bats, the leaf-nosed and vampire bats, the free-tailed bats, the mustached bats, and the evening bats. These bats are smaller in body size than the nonecholocating fruit bats and flying foxes (formerly Megachiroptera) and have diverse diets, including insects, blood, fruit, nectar, and small animals. They use echolocation to identify and classify objects as prey or non-prey and to avoid obstacles in their flight paths. Because echolocating bats are nocturnal, hearing is their primary sense for orienting and foraging. Their cognitive capacities can be understood through how they use echolocation to learn about and perceive their environment. This review will approach the issue of cognition through studies of perception, learning, and memory; communication and navigation are addressed in other entries.

## Active Perception

Echolocation is an active sense by which bats make ultrasonic (20–100 kHz) sounds in their larynx, beam them into the environment through their nostrils or open mouths, and then process the returning echoes to form an image of (to “see”) their surroundings (Griffin 1958). Bats modify their echolocation calls in order to adapt to their immediate situation. They change the rate at which they emit these calls as they simultaneously pursue insects and avoid obstacles, and they change the direction in which they point their echolocation sound beam to ensoundify (“look at”) different objects in the environment. When and whether bats make these modifications depend on how much clutter (background or irrelevant objects) they must contend with (Moss et al. 2011). When many objects are present in the environment, for example, when chasing an insect in vegetation, the flying bat must separate out numerous echoes from various sources (the insect, the vegetation, other objects in the environment) arriving at its ears from multiple directions. This means that the bat must decide which echoes are relevant for foraging (those that represent the insect) and those that are relevant for orientation (those that represent vegetation and obstacles), and then coordinate its perception of these echoes with its control of flight in order to be able to make a successful capture without crashing.

Big brown bats (*Eptesicus fuscus*) pursuing a flying insect in an open, uncluttered environment will call progressively faster and faster, emitting from 10 up to 200 sounds per second with shorter and shorter interpulse intervals (100–20 ms) as they progress through the basic prey-interception sequence of search, pursuit, and capture (Simmons et al. 1979). Bats modify this basic sequence of sound emissions when flying and foraging in cluttered surroundings. In one experiment, big brown bats were challenged with flying in a large, dark flight room with multiple obstacles impeding their flight paths (Petrites et al. 2009). As the environment became more and more cluttered with obstacles, the bats called more and more rapidly, and the standard interception sequence changed as a result. When few obstacles

impeded their flight paths, bats made echolocation calls with interpulse intervals of about 40–100 ms, which are indicative of search and pursuit phases. Conversely, when many obstacles were present, interpulse intervals decreased to 15–65 ms, indicative of pursuit and capture phases. The duration of interpulse intervals is a metric of how perceptually challenging or difficult the bat finds its environment, and how rapidly it must update its image of the environment to stay on its flight path. Moreover, when flying in a cluttered environment but not in an open environment, bats emit their calls in discrete groups called “sonar sound groups” rather than in one smooth decreasing sequence. In a sonar sound group, groups of two, three, or four sounds are emitted close together at very short interpulse intervals (15–25 ms), and these groups alternate with groups of other sounds made at longer interpulse intervals (25–60 ms). Thus, a bat may make a cluster of four sounds separated by very short interpulse intervals followed by a cluster of two sounds separated at longer intervals. The bat repeats this alternating sequence of clusters of short interpulse intervals flanked by longer interpulse intervals until it reaches its goal. These sonar sound groups have been compared to strobe groups in vision and act in much the same way – to provide a burst of rapid images to allow continual updating of the internal percept of the environment (Moss et al. 2011).

The direction towards which the bat points its echolocation beam is another index of its percept of its surroundings. Bats can rapidly change the direction of their beam when hunting and orienting simultaneously in cluttered environments. For example, studies have shown that Japanese house bats (*Pipistrellus abramus*) can manage to hunt insects in a busy urban environment by directing their beam at multiple targets (insects, buildings, telephone poles, bridge supports) while simultaneously navigating in-flight (Fujioka et al. 2014). The bats were able to point their echolocation beams both in the momentary direction of their own flight and also towards the direction of the flying insect (Fig. 1). Moreover, they were able to direct their echolocation beam to new insects appearing in the immediate vicinity,

**Microchiroptera Cognition, Fig. 1** Horizontal-plane view of a looping flight path (start to end) followed by an individual Japanese house bat pursuing two small flying insects outdoors. The bat's flight path is traced by the orange line; its flight direction is shown by the orange arrows and the successive silhouettes of the bat. The blue arrows show the direction in which the bat pointed its echolocation beam each time it made a call. In this example, the bat captured two insects (1st capture, 2nd capture). The rapid change in direction of the echolocation beam shows evidence of the bat planning its flight to capture the second insect after it has encountered and captured the first insect. Total duration of the flight is less than 4 s. (Data are adapted and replotted from Fujioka et al. (2014))

suggesting that the bats were simultaneously planning their flight towards these new prey while still keeping the original prey and surrounding obstacles in view. These rapid shifts in the direction of the echolocation beam suggest that bats are able to divide their attention between separate objects and can anticipate when and where new objects might appear. Bats have an awareness of their environment and modify their echolocation behavior as a result.

### Individual Variability in Perceptual Strategies

Individual bats face the challenges of their environment in unique ways. Even though all bats modify their echolocation behavior in the ways

described above – changes in interpulse intervals and in direction of the echolocation beam – individuals differ in the extent to which they make these modifications. For example, four bats flying through the same cluttered environment altered the pattern of interpulse intervals of their echolocation calls in different ways, even though all bats solved the orientation task successfully (Fig. 2). Some bats made sonar sound groups consisting of alternations of four calls with two calls, while other bats made sonar sound groups consisting of alternations of two calls with one call. Moreover, the bats' expectancy of their environment was reflected in how rapidly they made their calls. When the bats were challenged with flights through expected (matching that on the previous trial) compared to unexpected (new) obstacle arrays of different configurations, both their interpulse intervals and the pattern of sonar groups differed in the two environments (Accomando et al. 2018). All four bats made unique modifications, indicating that their individual expectancy of the environment altered their percept. This shows the flexibility of their behavior.

### Associative Learning

Echolocating bats have demonstrated the ability to learn in various instrumental tasks. They are readily trained in two-choice or go/no-go procedures for food reward. Using echolocation alone, bats can learn to discriminate objects differing in size, shape, orientation, and distance. They can also learn to associate a virtual (phantom) object with a specific location in space based solely on echo information. Bats can discriminate simple echoes (that is, containing one main reflection or "glint") from more complex echoes (containing many glints). This is likely achieved by analyzing and comparing the acoustic information in these echoes rather than by simply counting glints.

Bats' ability to learn is correlated with the complexity of their natural foraging behaviors. One study compared behavioral flexibility and rule-learning strategies in three species of the

**Microchiroptera Cognition, Fig. 2** Individual big brown bats emit echolocation calls in different patterns (sonar sound groups) while flying in the same challenging environment. **A** shows the output of a similarity (SSIMS) algorithm applied to the analysis of echolocation call patterns (interpulse interval timing and sonar sound groups) of individual bats. Lower values of the normalized SSIMS distance (x axis) show greater similarity. In this example, the normalized distance is more similar within (black outlines and triangles) than between (gray outlines and triangles) individual bats. The y axis shows the percentage of the total between-trial comparisons made (i.e., the relative

frequency of each normalized distance). The black and gray distributions are significantly different, showing that individual bats were internally consistent in their calling patterns, but that these patterns differed across bats. All bats completed the flights successfully. **B** shows the individual results for each bat (red = Bat 1, green = Bat 2, blue = Bat 3, and black = Bat 4). It is clear that the echolocation calls of each bat clustered differently in the similarity space, with very little overlap. (Data are modified from Accomando et al. (2018) by a Creative Commons Attribution License)

genus *Myotis* challenged with the same experimental tasks (Clarín et al. 2013). All three species learned a simple maze at the same rate and with the same success. But the performance of these three species differed when faced with a complex maze and when the rules for solving the maze changed. In the complex maze, the long-fingered bat (*Myotis capaccinii*), a species that hunts insects over open water, showed poorer performance than did Geoffroy's bat (*Myotis emarginatus*), a species that hunts insects in dense vegetation. When the rules for solving the complex maze were changed, Geoffroy's bat learned these new rules more quickly than the long-fingered bat. Hunting in dense vegetation is a more complex foraging strategy than hunting over open water because it requires bats to avoid more obstacles, to segregate more echoes, and to implement more complex flight paths. Bats using

the more complex strategy may require increased cognitive flexibility to find and locate prey.

## Social and Observational Learning

Bats are able to solve problems and gain information about the environment by observing other bats. Big brown bats, little brown bats (*Myotis lucifugus*), and pallid bats (*Antrozous pallidus*) can learn a novel feeding task simply by watching other bats perform this task (Gaudet and Fenton 1984). Bats can learn novel tasks from watching other bats perform, even when these novel tasks require reversal of a previously learned discrimination. Fringe-lipped bats (*Trachops cirrhosus*) prey on túngara frogs (*Physalaemus pustulosus*) and locate these edible prey by listening to the frogs' advertisement

**Microchiroptera Cognition, Fig. 3** Big brown bats flying in an unfamiliar flight room form individualized flight paths. The bats had to avoid obstacles in the room to maintain a steady flight path. Both bats were flown for 60 trials on each of 6 consecutive days. The flight paths (blue lines, red dots) were quantified by marking when and

where the bats made echolocation sounds. As time progresses from Day 1 to Day 6, the flight paths of the two bats become more distinct and more stereotyped. Although both bats flew successfully in the same environment, their flight paths are different. (Archival data from Barchi et al. (2013))

(mating) calls. The bats learn to associate the sound of the frogs' calls with edible food. Similarly, in the natural environment, these bats learn to avoid the advertisement calls of cane toads (*Bufo marinus*) because these toads are toxic. However, studies were able to show that fringe-lipped bats can learn to associate cane toad calls with edible prey instead of toxic prey, if they are rewarded with edible prey for approaching those calls. Moreover, naïve bats were able to learn this novel association between food and cane toad calls after observing bats who had already been trained, without having been explicitly trained themselves (Page and Ryan 2006). Neotropical short-tailed fruit bats (*Carollia perspicillata*) can also learn a preference for a novel food, this time from observing tutor bats within their roosts (Ratcliffe and ter Hofstede 2005). Because bats are social animals that roost, fly, and forage in groups, social learning is likely widespread across species.

## Memory

Because the operating range of echolocation is short and constrained by the physics of the attenuation of ultrasonic sounds in air, and because bats can fly quickly, having a sense of and memory for space would be extremely advantageous for orientation and flight. Many bats follow predictable routes when flying between their roosts and their foraging grounds. But, if novel obstacles are placed along these familiar routes or if familiar

objects are removed, the bats will crash into these objects or turn back. These behaviors suggest that bats have an internal map of their environment (Griffin 1981). How big brown bats might form such an internal map was examined in a series of experiments in which naïve bats were released over a series of days into a large, dark, unfamiliar flight room containing obstacles that the bat needed to avoid to maintain a steady flight path (Barchi et al. 2013). Each bat quickly developed an individualized, stereotyped flight path around the flight room that persisted over days (Fig. 3). When the bat was reintroduced into the flight room after a long absence, it immediately flew along this same flight path, indicating that it recognized the space and remembered its flight path through the space. These data are consistent with the hypothesis that bats have a spatial memory and an internal cognitive map of space. They also show individual variability in this spatial memory.

Even though insect-eating bats can form a spatial memory for orientation, when foraging, echo cues from prey (which give information on prey size and shape) take precedence over spatial (location) cues. Studies have shown that the insect-eating Natterer's bat (*Myotis nattereri*) bases its foraging decisions on echo cues rather than on spatial location cues when these two cues are put into opposition (Hulgard and Ratcliffe 2014). Because insects fly, their specific locations change continually, and so learning their spatial locations will not be as beneficial a strategy as learning their echo signatures and anticipating their flight paths. Spatial memory for location is

more salient for bats foraging on flowers and fruits. Pallas' long-tongued bat (*Glossophaga soricina*) feeds on nectar. These bats learn the locations of patches of flowers, likely using visual and olfactory cues, but will not revisit a particular flower within a patch until after sampling the other flowers in that patch. In this way, they can avoid foraging from a flower whose nectar has been recently depleted. When location (spatial) cues are put into conflict with echo (size/shape) cues, Pallas' long-tongued bats pay more attention to the spatial cues than to the echo cues (Thiele and Winter 2005). Foraging strategies impact the extent to which a bat uses its spatial memory.

## Conclusion

Echolocating bats learn to identify objects and to distinguish edible from inedible prey by associating echoes from these objects with their physical characteristics. While flying, they can shift their attention between simultaneous and sequential moving insect prey while still maintaining a flight path around obstacles. They can create and update internal maps of space. They can learn to respond to virtual echoes (that is, ones in which no objects are physically present). They can remember which flowers they have recently visited and which may still contain nectar. These are all important aspects of cognition. Other aspects of cognition have not been examined systematically in echolocating bats. It is not known, for example, if bats form categories of events apart from their ability to recognize and discriminate echoes.

Echolocating bats were used by the philosopher Thomas Nagel (1974) as an example of a mammalian species that experience their world and therefore have conscious mental states, even though these experiences are not directly accessible to humans. It is not known if bats are conscious or if they experience metacognition. But because echolocation is an active sense, bats must have an awareness of their surroundings in order to implement the dynamic changes in their calls and in their echolocation beams that occur in complex environments. The presence of strong individual differences between bats in how and

when they modify their echolocation calls and in how they represent space also suggests that these animals have individual awareness.

## Microchiroptera Diet

Nathália Siqueira Veríssimo Louzada<sup>1</sup> and Anne Caruliny do Monte Lima<sup>2</sup>

<sup>1</sup>Programa de Pós-graduação em Biodiversidade e Biologia Evolutiva, Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

<sup>2</sup>Instituto de Biologia, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil

## Introduction

Microchiroptera is a traditional suborder of bats that includes all species that echolocate. No longer recognized as a suborder, the microbats are now split into Yangochiroptera (14 families, 158 genera, and 866 species) and Yinpterochiroptera, being represented in the latter by Rhinolophoidea (6 families, 17 genera, and 183 species) (Amador et al. 2016). Microbats encompass representative species from all bats' acknowledged diet categories. Most of the families are insectivores, but a lot of species feed on fruits (and seed/leaves), nectar

(and pollen), small vertebrates (including fish and other bats), several arthropods (e.g., scorpions, centipedes, spiders, crustaceans), and blood (Neuweiler 2000). The difference in feeding habits is so marked that in the earliest classifications proposed for Chiroptera, the former suborders Megachiroptera and Microchiroptera were, respectively, called Fructivorae, Carpophagen, or Frugivora and Insectivorae, Entomophagen, or Animalivora (Gardner et al. 1977). In Yangochiroptera, the largest variety of dietary specializations occurs in the family Phyllostomidae that, besides insectivory, includes frugivory, nectarivory, carnivory, and sanguivory. Curiously, the etymology of some bats' genus of this family reflects their feeding habits: *Diaemus* (*diaimos* (Gr.): blood-stained), *Musonycteris* (*musa* (Ar.): banana), and *Glossophaga* (*gloss-glossa* (Gr.): tongue + *phag-phago* (Gr.): to eat). The epithet *mordax* (La.) in *Lonchophylla mordax* and *Sturnira mordax* refers to biting. Many names (e.g., *Vampyrum*, *Vampyrops*, *Vampyrodes*, and *Vampyressa*) are associated with the initial idea that all bats fed on blood (Gardner et al. 1977). Vernacular names often refer to feeding habits as well. Some examples are “Common Vampire Bat” (*Desmodus rotundus*), “Great Fruit-eating Bat” (*Artibeus lituratus*), and “Vieira's Nectar-feeding Bat” (*Xeronycteris vieirai*).

## Dietary Categories

Despite the general classification of bats into several dietary categories, many of them do not restrict their diet just to one type of food (Table 1). Many insectivores, for example, also feed on other arthropods and may complement their diet with fruits and small vertebrates. Similarly, the frugivores may consume nectar, floral parts, and even insects (Rex et al. 2010; Monteiro and Nogueira 2011; Reis et al. 2017). Rex et al. (2010) demonstrated that phyllostomids are “opportunistic omnivores” and complement their primary diet with nutrients from many different food sources, which is important to satisfy the protein and carbohydrate requirements for growth, tissue synthesis, and

**Microchiroptera Diet, Table 1** Primary diet of microbats' families, including phyllostomid subfamilies

| Family           | Diet                     | Family          | Diet                     |

<sup>f</sup>*Nycteris grandis* eats small vertebrates

<sup>g</sup>Some *Myotis* eat fish

reproduction. This ability to switch among several food types also helps them survive in periods of scarcity of their preferred food (Rex et al. 2010). Even so, some species are more food specialized and have a more restrict diet (e.g., *Dermanura*, *Pygoderma*, *Desmodus*) or consume just occasionally other resources (e.g., *Macrotus*, *Lonchorrhina*, *Trinycteris*) (Monteiro and Nogueira 2011; Reis et al. 2017). In these cases, the over-consumption of the same sources, such as fruits by herbivorous bats, may allow them to meet their protein requirements when eating a protein-poor diet. Bats also may adjust their diets to local and seasonal changes in resource availability (Rex et al. 2010).

The diet has been used, together with habitat and foraging mode, to classify bats into ecological guilds. According to Root (1967), “a guild is defined as a group of species that exploit the same class of environmental resources in a similar way.” This classification varies among authors, from simpler categories to more complex ones (e.g., Norberg and Rayner 1987; Kalko et al.

1996). More recent studies, however, do not take into account the diet on the guild classification “because echolocation and foraging behavior are mainly influenced by habitat type and foraging mode but not by the prey type” (Denzinger and Schnitzler 2013). Considering the importance of earlier guilds classifications, below we present data for the main dietary categories of microbats, classifying them primarily according to their predominant food consumed, but also addressing their foraging strategies and correlated morphological characteristics.

## Insectivores

Most bats feed on insects, but other invertebrates, such as crustaceans, spiders, and scorpions, may also be part of their diet. The taxa of insects most consumed by bats are Lepidoptera, Coleoptera, Diptera, Hemiptera, Hymenoptera, and Orthoptera (Kunz and Fenton 2005; Reis et al. 2017). The hardness of the prey eaten varies from soft (e.g., lepidopterans) to hard (e.g., coleopterans),

and the capacity of these bats to feed on harder prey depends on their skull size, teeth morphology, and bite force. Larger bats may consume a wider range of insects' sizes, including the hard-bodied ones (e.g., beetles) since they have more robust skulls and larger teeth (Freeman 2000; Aguirre et al. 2003).

The way bats capture their prey also varies; some species catch insects on the wing during flight (aerial insectivores) and others take prey from the substrate (gleaning insectivores). The gleaners generally locate their prey using the sound generated by them while the aerials use oral echolocation (Kunz and Fenton 2005; Santana and Cheung 2016). A more specific classification was proposed by Norberg and Rayner (1987) that described five foraging strategies for the insectivore's bats. The *fast hawking* comprises bats which rely on speed and agility to catch insects away from clutter, at high speeds and altitude, using echolocation to detect the prey at long range. As examples are some molossids, emballonurids of genus *Taphozous*, vespertilionids of genera *Nyctalus* and *Lasiurus*. The *slow hawking* comprises bats with a sustained flight, slow speed maneuverability, and agility that locate their prey by echolocation at short range. Some examples are *Emballonura* and *Rhynchonycteris* (Emballonuridae), many mormoopids, natalids, thyropterids, nycterids, megadermatids, rhinolophids, *Macrotus* (Phyllostomidae), and some vespertilionids (e.g., *Lasionycteris*, *Nyctophilus*, *Eptesicus*). The *trawling* comprises species that feeds opportunistically on many insects that swarm over water and species that actually have a more specialized pattern of trawling for aquatic insects. This is seen in many species of *Myotis* (e.g., *M. albescens*, *M. daubentonii*, *M. capaccinii*, *M. velifer*), in the noctilionid *Noctilio albiventris*, and in the phyllostomid *Macrophyllum macrophyllum*. The *gleaning* and *hovering* include bats that glean from the ground, requiring the ability to handle prey on the ground and often to fly off with it, and bats that hover briefly while searching for food or while gleaning from vegetation or trunks. Many vespertilionids present hover-gleaning (e.g., *Myotis evotis*, *Myotis myotis*, *Plecotus auritus*), some nycterids, *Craseonycteris thonglongyai*

(*Craseonycteridae*), and many of the smaller insectivorous phyllostomids. For the ground-gleaners, some examples are *Nycteris thebaica* (Nycteridae), *Antrozous pallidus* (Vespertilionidae), *Cardioderma cor*, *Megaderma lyra*, *Macroderma gigas* (Megadermatidae), and larger insectivorous phyllostomids (e.g., *Macrotus californicus*). This strategy allows bats to catch insects and other terrestrial arthropods before they run away and, like the hover-gleaners, they need slow and maneuverable flight. The large ears of some gleaners enable them to use low-intensity echolocation calls or to hear sounds from prey. The *flycatching* and *perch hunting* comprises bats that hawk flying insects by making short flights from a perch or use a perch while seeks non-flying prey, respectively. These bats have a good maneuverability, increased agility and, like gleaners, have large ears. The *perch hunting* is seen in some vespertilionids (e.g., *Nyctophilus bifax*) and megadermatids (e.g., *Cardioderma cor*, *Macroderma gigas*). The *flycatching* is seen in some rhinolophids (e.g., *Rhinolophus* sp.) and larger hipposiderids (*Hipposideros* sp.).

## Carnivores

Bats that regularly feeds on vertebrates (frogs, reptiles, small birds, and terrestrial mammals, including other bats), except fish, using a wide range of hunting strategies, including ambushing prey, capture in continuous flight and gleaning from substrates (Norberg and Rayner 1987; Kunz and Fenton 2005; Santana and Cheung 2016). All carnivorous bats are osteophagous, consuming the bones of their prey along with the soft tissues (Santana and Cheung 2016). They do not always rely on their nasal echolocation for prey discrimination and search in the passive mode (listening and vision) for prey moving on the ground (Denzinger and Schnitzler 2013; Santana and Cheung 2016). Kalko et al. (1999) noted that *Trachops cirrhosus* hunts in continuous flight, changing gradually to perch hunting, and capturing frogs by mouth. It includes few species, some of which are only partly carnivorous (e.g., *Nycteris grandis* (Nycteridae) and the phyllostomids *Phyllostomus hastatus*, *Trachops*

*cirrhusus*, *Chrotopterus auritus*, and *Vampyrum spectrum*; Norberg and Rayner 1987; Reis et al. 2017). Santana and Cheung (2016) highlighted that large body size is not a requirement for the consumption of vertebrate prey in bats, once *Micronycteris microtis* (a small phyllostomid bat; 7 g) has been documented to feed on small lizards.

## Piscivores

Some bats, such as *Noctilio leporinus* (Noctilionidae), *Myotis vivesi*, and *Myotis capaccinii* (Vespertilionidae), regularly eat fish, but also supplement their diets with arthropods, like aquatic and nonaquatic insects, and some crustaceans (Norberg and Rayner 1987; Ferrarezzi and Gimenez 1996; Kunz and Fenton 2005; Aizpurua et al. 2015). They have a greatly enlarged hind feet and sharp claws that they use to trawl the water surfaces (Norberg and Rayner 1987). Piscivores bats find their prey using oral echolocation, but fish can only be detected when they break the water surface, as bats cannot echolocate entirely submerged targets (Schnitzler et al. 1994). Schnitzler et al. (1994) show that *Noctilio leporinus* can discriminate between the acoustical glint pattern produced by a fluttering insect and from a jumping fish, which can also produce low-frequency splashing while leave and enter the water, and could alert the bats. Aizpurua et al. (2015) demonstrated that *Myotis capaccinii* “react only to targets protruding above the water and discern fish from insects based on prey disappearance patterns.”

## Frugivores

Although some bats eat fruit as an alternative food (e.g., *Mystacina tuberculata* (Mystacinidae), *Noctilio albiventris* (Noctilionidae)), frugivores belong primarily to Phyllostomidae, more specifically to Stenodermatinae, Carollinae, and Rhinophyllinae. *Carollia* and *Rhinophylla* feed on fruits of *Piper*, *Solanum*, *Vismia*, *Cecropia*, *Ficus* and complement their diet with insects

and other plant resources (Monteiro and Nogueira 2011; Reis et al. 2017). The dietary preferences of stenodermatines vary among genus, where some have most of the diet composed of fruits (*Enchistenes*, *Dermanura*, *Ariteus*, *Stenoderma*, *Centurio*, *Pygoderma*, *Sphaeronycteris*, and *Ametrida*) and other are more generalists and complement their diet with pollen/leaves/nectar and insects (*Artibeus*, *Sturnira*, *Chiroderma*, *Vampyriscus*, *Vampyressa*, *Vampyrodes*, *Platyrrhinus*, *Uroderma*, and *Mesophylla*) (Monteiro and Nogueira 2011; Reis et al. 2017). A specialized type of frugivory is seen in some species of *Chiroderma* (*C. doriae* and *C. villosum*) that feeds on seeds of *Ficus*, “ingesting the rich nutrient content of seeds and discarding most of the coat fragments as compact oral pellets” (Nogueira and Peracchi 2003). Some stenodermatines feed on leaves – *Artibeus planirostris* feeds at least 16 species of plant leaves in Caatinga (Cordero-Schmidt et al. 2016) and *Platyrrhinus lineatus* regularly consumes leaves in dry and wet seasons in a fragment of Atlantic forest (da Rocha et al. 2017). The size of the specimen is reflected in diet – smaller species tend to eat smaller fruits and larger species tend to eat larger fruits (Kalko et al. 1996).

Frugivorous species can be classified in three foraging guilds, “canopy frugivorous” (forage above 3 m from the ground, on fruits in the trees of the canopy and subcanopy; e.g., *Artibeus*, *Uroderma*, *Chiroderma*), “groundstory frugivores” (forage on fruits of shrubby plants, from 0 to 3 m above ground level; e.g., *Carollia* spp.), and “scavenging frugivore (or juicers)” (feed on very soft ripe fruit) (Kalko et al. 1996).

As in gleaning insectivores, they use sensory cues, mostly olfaction, to detect and glean fruits from foliage of trees and shrubs, and use echolocation mostly for orientation in space (Kalko et al. 1996). Some stenodermatines (e.g., *Sturnira* and *Artibeus*) are also reported to feed on ripe fruit fallen on the ground (Gardner et al. 1977). They usually must commute long distances between foraging and roosting places, thus contributing to seed dispersal, and most species cling or perch while feeding (Norberg and Rayner 1987).

## Nectarivores

Nectar-feeding bats are found in Phyllostomidae, more specifically in Glossophaginae and Lonchophyllinae. These bats are excellent hoverers, typically hovering while feeding, and are distinguished by their greatly elongated rostrum and tongues, which are used to access the nectar of plants (Kunz and Fenton 2005; Fleming et al. 2009). They pollinate flowers with particularly characteristics that “appear to have evolved to attract relatively large, nocturnal, color-blind, volant pollinators” (Fleming et al. 2009). These characteristics, called “chiropterophilous syndrome,” include musty/fetid odor (given by sulfur-containing compounds), drab coloration (e.g., white, brown, green, pink, fuchsia, yellow), which may function to stand out the flowers against foliage at the night or as a camouflage from other visitors, and nocturnal anthesis (“opening of flower buds in the late afternoon or at night”; Fleming et al. 2009).

The flowers visited by nectar-feeding phyllostomids are often large and robust, more tubular in shape, and produce relatively large amounts of hexose-rich nectar. An important characteristic that allows bats to access the flowers is their placement away from foliage, emerging on branches or tree trunks (cauliflory) or suspended on long stalks (flagelliflory), allowing bats easily find, approach and depart from them (Fleming et al. 2009). Among the families of plants visited by nectar-feeding bats are Bromeliaceae, Brasicaceae, Fabaceae, Lythraceae, Magnoliaceae, Malvaceae, and Solanaceae (Reis et al. 2017).

An interesting behavior is recorded to some species that can forage in groups and exploit the resource more efficiently by following leader bats, saving energy, since just the leader appears to use echolocation (Kunz and Fenton 2005). Besides nectar, many species (e.g., *Anoura geoffroyi*, *A. caudifer*, *Brachyphylla* sp., *Glossophaga soricina*, *Leptonycteris curasoae*) also consume and digest pollen and parts of the corolla of flowers. Fruits and insects are usually present in their diet (Gardner et al. 1977; Ferrarezzi and Gimenez 1996; Fleming et al. 2009; Monteiro and Nogueira 2011; Reis et al. 2017).

## Sanguivores

Also known as vampire bats, the sanguivores are represented only by three species, *Desmodus rotundus*, *Diaemus youngi*, and *Diphylla ecaudata*, from the subfamily Desmodontinae (Phyllostomidae). They feed nearly exclusively on blood, being perhaps the most specialized feeding habit found in bats (Ferrarezzi and Gimenez 1996) and, as a consequence of this specialization, they are also the most agile quadrupedal bats (Schutt and Simmons 2006). *Diphylla* and *Diaemus* are arboreal foragers, feeding preferentially on avian blood, which is obtained from perching birds, stalked from below as they sleep. *Desmodus* feeds on mammals' blood (e.g., bovids, equids, porcines, and domestic animals), foraging both on the ground and trees, approaching the prey from above (Ferrarezzi and Gimenez 1996; Schutt and Simmons 2006). These bats have “trigeminal nerve fibers that innervate specialized pit organs” on their face, providing “the ability to detect infrared radiation as a mean of locating hotspots on warm-blooded prey” (Gracheva et al. 2011).

According to Neuweiler (2000), *Desmodus* locates a highly vascularized area of its prey, as the neck and throat, wets it with its saliva, and then presses its lower jaw against the skin. It then brings the upper jaw teeth down and cuts away a piece of skin. The wound reaches down into the dermis and bleeds for a considerable time because the vampire continually prods the wound with its rough keratinized tongue, opening new capillaries, and their saliva contains substances that prevent clotting. When vampire licks, the lower lip rests against the edge of the wound and the grooves on the left and right underside of the tongue allows the blood to flow through the split in the lower lip. A blood meal lasts about 25 min and the vampire can ingest about half of its body weight.

An interesting behavior seen in vampire bats is the altruism. Vampires do not accumulate large fat reserves and can survive no more than 3 days without blood meal, so vampires that have fed will regurgitate a part of their blood meal not only for their young, but for other adult members

of the colony that have failed to obtain a meal (Neuweiler 2000).

## Morphological Characterization

The morphology of the skull and teeth in bats is strongly linked to their diet (Neuweiler 2000; Santana et al. 2011). Microbats are almost exclusively insectivorous, except for Phyllostomidae. In insectivorous bats, the premolars and molars are located far back in the jaw, just under the muscles of mastication, where the greatest force can be applied. The molars are dilambdodont (W-shaped), the upper are sharply serrated, with narrow triangular ridges and grooves that fit tightly on the lower teeth (Neuweiler 2000; Santana et al. 2011). The morphology of the skull is also relevant and is correlated with the degree to which hard (robust skull) or soft (gracile skull) items occur in their diet (Freeman 2000). The durophagy (*duro* = hard + *phagous* = feeding) evolved independently in five families (Molossidae, Vespertilionidae, Emballonuridae, Noctilionidae, and Phyllostomidae) that share some morphological features: “stout dentaries, tooththrows with fewer but larger teeth, the development of cranial crests, usually longer canines relative to maxillary tooththrow length, and usually wide skull widths relative to skull lengths” (Freeman 2000). On the other hand, the soft-items specialized bats present “long thin jaws, gracile skulls with little or no cranial crest development, more but smaller teeth, and smaller canines” (Freeman 2000). Piscivorous bats have a teeth morphology similar to those of insectivores and a short, broad, and tall rostrum (Santana and Cheung 2016).

The greatest variation of skull and dental morphology is observed in Phyllostomidae. From an insectivorous ancestor, four major ecomorphological novelties evolved – carnivory, nectarivory, frugivory, and sanguivory. Carnivorous bats have enlarged cusps on their molars and teeth that are larger relative to the size of the palate, features that may aid mastication of endoskeleton items (soft outside, hard inside). The skull is generally robust, with well-developed

sagittal crest (Freeman 2000). Nectarivores have the rostrum narrow and elongated, the teeth reduced (in number and size), and a specialized protractible tongue that may even exceed their body length and are covered with long hair-like papillae (in Glossophaginae) or have deep longitudinal grooves running laterally along their entire length (in Lonchophyllinae) (Reis et al. 2017). Frugivorous bats from Stenodermatinae have short and wide rostrum and specialized teeth for processing fruit, with the molars large and broad (enlarged transversely); Carollinae is less specialized, with a tooth morphology resembling those of insectivorous bats (Freeman 2000). Sanguivorous bats have large and sharp incisors, large canines, and a great reduction in size and number of molars. The rostrum is extremely short and they have lateral grooves on their tongues, which allow the blood to flow during the feeding (Neuweiler 2000; Reis et al. 2017).

## Ecological Importance

Due to their food habits, bats can play several important roles in the ecosystems where they live. Fruits and flowers, for example, are important components in the diet of many phyllostomids and some species, such as *Phyllostomus hastatus*, play an important function in both flower pollination (chiropterogamy) and plant dispersion (chiropterochory) (Gardner et al. 1977).

Indeed, bats can be considered the most important seed dispersers among mammals, which is associated with their great mobility and foraging habits (Reis et al. 2007). According to Galindo-González (1998), frugivorous phyllostomids usually forage long distances searching for food. Once the fruits are collected, they go to refuges to consume and digest them. They are able to consume and disperse seeds of several sizes; when eating fruits with small seeds, the bat can easily swallow the fruit and the seeds will be expelled, after digestion, at the refuge or somewhere else. On the other hand, bigger seeds that cannot be swallowed will be released at the refuge after the consumption of the fruit pulp. In both

cases the seeds are released far from where the fruit was obtained, favoring its dispersion. The chiropterochory occurs in several families of plants (e.g., Moraceae, Piperaceae, Arecaceae, Anacardiaceae, Sapotaceae, Solanaceae, Meliaceae) and several frugivorous phyllostomids (e.g., *Carollia perspicillata*, *Artibeus lituratus*, *Vampyroides caraccioli*) are responsible for neotropical forests regeneration, once they help plants with their reproduction, colonization, and settlement (Galindo-González 1998). Some species (e.g., *Carollia sowelli*, *Artibeus jamaicensis*) are also important in perturbed areas (e.g., affected by forest fires), contributing to the germination of pioneer and persistent plant species, such as *Solanum erianthum* and *Psychotria* sp., which in turn generate microclimates for the short-term establishment of other plant species, encouraging the succession process (Preciado-Benítez et al. 2015).

The chiropterogamy is extremely important for plants and some bats have a deep relationship with the plants they pollinate (Kunz and Fenton 2005; Fleming et al. 2009). *Glossophaga longirostris* has a mutualistic relationship with columnar cacti (e.g., *Stenocereus griseus*, *Pilosocereus tillianus*), acting as their main pollinator, and *G. soricina* is an important pollinator of endemic plants of Atlantic forest, such as *Dysochroma viridiflorum* (Solanaceae) and *Pitcairnia albiflos* (Bromeliaceae). An interesting example occurs with *Anoura fistulata* (subfamily Glossophaginae). This bat can extend its tongue twice as far as those of other nectarivorous bats, being the unique species that can reach and pollinate the 8–9 cm long corollas of the *Centropogon nigricans* (Campanulaceae), which appears to be an example of plant-pollinator coevolution (Muchhala 2006). In general, bats have an important role on pollination of nearby 500 species of plants in Neotropics, a lot of them with commercial value, as food (e.g., *Caryocar* sp., *Psidium* sp., *Musa* sp.) or as ornaments (Reis et al. 2007).

Insectivorous bats are important in the insect's population control. Some species can eat a huge number of insects on a single night, corresponding sometimes to almost twice its weight, and some phyllostomids can capture up to 500 insects per hour. Thereby, bats that usually feed on dipterans

can help on control of some diseases' vectors (e.g., *Aedes aegypti*) (Reis et al. 2007). Additionally, some bats (e.g., *Rhinolophus*, *Plecotus*, *Nyctalus*, *Myotis*, *Eptesicus*) act as natural pest controllers, eating many lepidopterans that are considered important agricultural pests (e.g., Noctuidae and Nymphalidae). This can provide a decrease of pesticide applications, also reducing the development of pesticide resistance, and some farmers in North America have been installing artificial roosts, such as bat boxes, trying to attract these bats for this service (Ricucci and Lanza 2014).

## Microchiroptera Life History

Fred Victor de Oliveira

Laboratory of Mammal Evolution, Department of Zoology, Universidade Federal de Minas Gerais, Belo Horizonte, Brazil

## Synonyms

[Bats](#); [Yimpterochiroptera](#); [Yangochiroptera](#); [Life cycle](#)

## Definition

Life history refers to the life cycle of an organism (how they are born, grow, reproduce, and die) and aspects that maximize their chance of survival and

reproduction, including morphological, physiological, and ecological traits.

## Introduction

Bats are mammals that belong to the order Chiroptera, which is the second most speciose group within the class Mammalia, only outnumbered by rodents. Bats can be found in nearly every part of the world inhabiting forests, savannas, tundras, mountains, deserts, urban and rural areas in temperate, subtropical and tropical latitudes, with the exception of polar regions and some oceanic islands (Vaughan et al. 2015). Bats are undoubtedly the most diverse group of mammals when it comes to feeding habits; their diet includes insects, other arthropods such as scorpions, spiders and centipedes, fruits, nectar, small vertebrates (e.g., fish, frogs, lizards, birds, and small mammals), and even blood (Vaughan et al. 2015).

Two features are responsible for the astonishing success of bats: they possess a sophisticated echolocation system and are the only mammals capable of true (or powered) flight. These traits promote good mobility and lead to the exploration of nocturnal niches that are largely unoccupied by other vertebrates (Altringham and Senior 2005). There are currently more than 1300 bat species classified in 21 families (Fenton and Simmons 2014; Foley et al. 2015; Amador et al. 2018). This number tends to increase at a rapid pace, and at least ten new species are described every year (Fenton and Simmons 2014). This great diversity is also reflected on morphology, ecology, social behaviors, and different attributes associated with the life history of bats.

## Microchiroptera x Megachiroptera

The order Chiroptera has been traditionally divided into the suborders Megachiroptera and Microchiroptera. Megachiroptera (megabats) contains just flying-foxes and fruit bats of the family Pteropodidae, usually large-bodied, non-echolocating species; while Microchiroptera

(microbats) comprises all remaining families of small-sized, laryngeal echolocating bats. However, this classification is outdated and does not reflect the evolutionary relationships of bat families, as shown by molecular studies (Springer et al. 2001; Teeling et al. 2005; Foley et al. 2015). Six families of microbats are more closely related to flying-foxes and fruit bats (Pteropodidae) than to the remaining families of microbats, what make Microchiroptera paraphyletic, hence Megachiroptera and Microchiroptera are artificial groups.

Bats are now classified based on molecular evidence into the suborders Yinpterochiroptera (containing the families Craseonycteridae, Hipposideridae, Megadermatidae, Pteropodidae, Rhinolophidae, Rhinonycteridae, and Rhinopomatidae) and Yangochiroptera (containing Cistugidae, Emballonuridae, Furipteridae, Miniopteridae, Molossidae, Mormoopidae, Mystacinidae, Myzopodidae, Natalidae, Noctilionidae, Nycteridae, Phyllostomidae, Thyropteryidae, and Vespertilionidae) (Springer et al. 2001; Teeling et al. 2005; Foley et al. 2015). The terms Megachiroptera/megabats and Microchiroptera/microbats are used in an informal way to distinguish and refer to Pteropodidae and the small-sized laryngeal echolocating bats, respectively.

## Natural History

Microchiropteran bats come in different shapes and sizes. The Kitti's hog-nosed bat, *Craseonycteris thonglongyai* (Craseonycteridae), is one of the smallest mammals in the world, weighting 2 g and with a wingspan of less than 20 cm, while the Spectral Bat, *Vampyrum spectrum* (Phyllostomidae), can weight more than 200 g and reaches a wingspan of nearly 1 meter (Vaughan et al. 2015).

Most microchiroptera families are insectivorous (e.g., Cistugidae, Craseonycteridae, Emballonuridae, Furipteridae, Hipposideridae, Megadermatidae, Miniopteridae, Molossidae, Mormoopidae, Mystacinidae, Myzopodidae, Natalidae, Noctilionidae, Nycteridae, Rhinolophidae, Rhinonycteridae, Rhinopomatidae, Thyropteryidae, and

Vespertilionidae). Greater Bulldog Bats, *Noctilio leporinus* (Noctilionidae), and some Mouse-eared Bats, *Myotis vivesi* and *M. macropus* (Vespertilionidae), use their large feet and claws to capture fish for food. Other vesper bats (*Ia io* and *Nyctalus spp.*) seasonally prey upon migratory birds, and Slit-faced Bats (Nycteridae) and False Vampire Bats (Megadermatidae) eat small vertebrates (Vaughan et al. 2015). New World Leaf-nosed Bats (Phyllostomidae) calls attention because they are the family with the most diverse feeding habits amongst all mammals: there are more than 200 phyllostomid species with several adaptations to frugivory (e.g., carolines, stenodermatines), nectarivory (e.g., lonchophylines and glossophagines), insectivory (e.g., micro-nycterines), carnivory (e.g., phyllostomines), omnivory (phyllostomines), and hematophagy (desmodontines) (Vaughan et al. 2015; Baker et al. 2016).

Microbats live in a great variety of natural environments, and some species can also adapt to inhabit urban areas. The urban landscape provides conditions for the establishment of bats, such as food resources (especially for insectivorous bats), and roost sites at human-made structures. Microbats are found in the wild roosting in caves, crevices, tree cavities, under tree bark, foliage, exposed on tree branches, or in any suitable shelters they find (Kunz 1982). Neotropical Disk-winged Bats (Thyropteridae) and Madagascar's Sucker-Footed Bats (Myzopodidae) possess suction discs and pads on their hind feet and wrists/thumbs to help roost inside the smooth surfaces of rolled leaves. Bamboo Bats, *Tylonycteris spp.* (Vespertilionidae), roost inside slits and cavities on bamboo stems, while the Hardwicke's Woolly Bat, *Kerivoula hardwickii* (Vespertilionidae) roosts inside modified leaves of pitcher plants. Some stenodermatine bats (Phyllostomidae) such as *Uroderma spp.*, and *Ectophylla alba*, modify leaves to make tents, and some phyllostomine bats (Phyllostomidae) such as the Greater Spear-nosed Bat, *Phyllostomus hastatus*, and Round-eared Bats, *Lophostoma spp.*, use their teeth to excavate arboreal termite nests where they may roost (Fenton and Simmons 2014).

As nocturnal animals, microbats forage mostly at night, but the time they emerge from their roosts

is variable among species; most emerge in the first hour after sunset, some a little earlier, and others later (Altringham and Senior 2005). Emergence time is related to vulnerability to predation, flight performance, feeding habits, and foraging strategies according to the species. Insectivorous bats usually emerge before dark when there is still some light available, and they can access diurnal and nocturnal insects (Altringham and Senior 2005).

The foraging area that bats use is also variable among species. Some microbats forage in small areas close to their roost, while others cover great distances every night when searching for food. Brown Long-eared Bats, *Plecotus auritus* (Vespertilionidae), forages only 1 km from its roost, while Brazilian Free-tailed Bats, *Tadarida brasiliensis* (Molossidae), forage up to 50 km away from their roosting sites (Altringham and Senior 2005). Bats can also forage alone or in small co-ordinated groups (e.g., *Phyllostomus hastatus*, *Rhynchonycteris naso*, and *Saccopteryx leptura*), according to the species (Altringham and Senior 2005).

## Life History

Life histories of microbats are very diverse in terms of life cycles, social systems, and mating strategies. Despite small in size, many aspects of their life history resemble those of large-bodied mammals: longevity, multiple reproductive events, few offsprings per pregnancy, intense parental care, and delayed onset of sexual maturity (Racey and Entwistle 2000). These traits are unusual for small mammals of similar size as bats (such as rodents), since they have rapid reproduction and high mortality rates.

## Social Systems

Sociability is a feature common to most microchiropteran bats, and social structure and social interaction play fundamental roles in their life history. Bats interact with each other using a wide array of sensory cues that include auditory,

**Microchiroptera Life**

**History, Fig. 1** A colony of Woolly False Vampire Bats (*Chrotopterus auritus*), a species that live in small family groups. (Author: Hugo Villela)

olfactory, tactile, and visual displays; and, although some microbats may be solitary, the majority of species are colonial (Fig. 1). Roosting in colonies may reduce predation risk through dissolution effect, reduce thermoregulation costs, and be beneficial in terms of cooperation and information transfer (Altringham and Senior 2005).

Colony size typically varies from few bats to a few hundred individuals, and larger colonies are found especially amongst cave-dwelling insectivorous species. Brazilian Free-tailed Bats, *Tadarida brasiliensis* (Molossidae), currently held the title of the largest mammal aggregations found in nature, and may form colonies of several millions bats in North, Central, and South America (Altringham and Senior 2005).

Colony size and composition may vary over time and suffer influence from many aspects such as mating strategies, seasonal changes in climate, food availability, reproductive status, and roosting ecology (Altringham and Senior 2005). Besides, social structures can be modified through fragmentation and fusion of groups, migration between harems and other types of colonies, spatial and temporal segregation of sexes and ages, weaning of juveniles, and other countless possibilities (Altringham and Senior 2005).

Some temperate zone species live in small groups formed by females and males (e.g., *Plecotus auritus*), and most species roost in

small colonies formed exclusively or mostly by females, with males living in small groups or solitary roosting (Altringham and Senior 2005). However, during hibernation, bats can roost alone, in mixed-sex or single-sex groups, and sometimes even in mixed-species groups (Altringham and Senior 2005). In many tropical and subtropical species, males form harems with females, such as in several New World Leaf-nosed Bats (Phyllostomidae) and Sac-winged Bats (Emballonuridae). On the other hand, a small number of species roost in pairs or extended family groups with their offsprings, such as some animalivorous False Vampire Bats (Megadermatidae) and New World Leaf-nosed Bats (Phyllostomidae).

The type of roost bats uses also influences the size a colony can reach (Altringham and Senior 2005). For example, thyropterids and myzopodids roost in temporary roosts such as rolled leaves, therefore they form nomadic small-sized colonies that must frequently relocate to new roosts when leaves unfurl. In contrast, bats that roost in permanent (e.g., caves) or long-lasting shelters (e.g., hollow trees) may form colonies of larger sizes (e.g., molossids, mormoopids, and vespertilionids).

Developed social behaviors are observed in the Common Vampire Bat, *Desmodus rotundus* (Phyllostomidae). They roost in colonies and die of starvation if they fail to feed in two nights, and,

### Microchiroptera Life

**History, Fig. 2** A colony of Common Vampire Bat (*Desmodus rotundus*), a species with highly developed social behaviors. (Author: Gabriela Rezende)

to avoid colony members from starving, bats share blood through regurgitation (Wilkinson 1990) (Fig. 2).

### Mating Systems

Like other aspects of their life history, microbats also have an astonishing diversity of mating systems. However, mating behaviors of bats, in general, are hard to be categorized because some classifications may be compartmentalization of a continuum instead of nonoverlapping categories (McCraken and Wilkinson 2000; Altringham and Senior 2005).

Mating systems can be categorized using many criteria such as the number of females and males within the mating group (composed either by single male/multiple females, multi-male/multiple females, or single male/single female), duration of association (e.g., groups are seasonal or persist year-round), compositional stability (e.g., a more or less stable female composition within harems), mating sites (e.g., in or away from the roost), and spatial distribution of sexes (e.g., in some species roving females visit males that roost alone) (McCraken and Wilkinson 2000).

Harems seem to be a common system for bats in general, and although most species show some form of polygyny (male mates with multiple females), polyandry (females mate with multiple males), promiscuity and monogamy are also present. In some species, there are even records

of multiple paternity and paternity outside mating groups. Besides, some species are not restricted to a single mating system, such as the Lesser Sac-winged Bat, *Saccopteryx leptura* (Emballonuridae), that is frequently monogamous but can also form harems (Altringham and Senior 2005).

Monogamy is reported for few microchiropterans and includes species that may roost in stable pairs, such as the Spectral Bat, *Vampyrum spectrum* (Phyllostomidae) and the Yellow-winged Bat, *Lavia frons* (Megadermatidae), but also gregarious species such as the Heart-nosed Bat, *Cardioderma cor* (Megadermatidae), that forms monogamous pairs within the colony (McCraken and Wilkinson 2000; Altringham and Senior 2005). In some species, the male and female remain together throughout 1 year, but during mating seasons new pairs are formed such as in the Benito Roundleaf Bat, *Hipposideros beatus* (Hipposideridae) (McCraken and Wilkinson 2000).

### Sexual Dimorphism and Mating Displays

Pronounced sexual dimorphism is rare among bats in general, and males and females are very similar in appearance. Usually, females are a little larger than males in most species of microbats. The size difference is remarkable in the Little White-shouldered Bat (*Ametrida centurio*), where males are much smaller than females

(17% of size difference) that they were once described in a separated species (Lee Jr. and Dominguez 2000).

Marked sexual dimorphism on qualitative external traits is also rare, and when present, males have more developed structures than females. On short-faced bats (a group of fruit-eating phyllostomids that also includes *Ametrida centurio*), it is common to find examples of notable sexual dimorphism: Visored Bats (*Sphaeronycteris toxophyllum*) has large fleshy protuberances above and between their eyes that are larger on males (Fig. 3). Wrinkle-faced Bats (*Centurio senex*), as its name suggests, have a naked face ornated with dermal outgrowths that are more prominent on males than those seen on females. Males Visored Bats and Wrinkle-faced Bats also possess a skin fold under their chin that extends to cover their faces, a feature rudimentary on females.

In microbats, males have several strategies to attract and mate with females, including vocalizations, olfactory clues, and visual displays according to the species. Territorial males can be aggressive with other males, and mark their territories with scents. In some species, however, males gather together to compete for female's attention using vocal and visual displays. In this behavior, known as lekking, the female chooses

the most attractive and healthier male to mate. Mating can be quiet and peaceful, but there are reports of males aggressively pulling females from a group and forcing them to copulate (e.g., *Tadarida brasiliensis*) (McCracken and Wilkinson 2000).

Scents play an important role in mating and also for communicating purposes. Glandular scent organs are present on the face, gular region, chest, ears, and other regions according to sex and the species (e.g., natalid organ in males Funnel-eared Bats (Natalidae) and eversible glandular organs in front of the noseleaf of males of some Old World Leaf-nosed Bats (Hipposideridae)) (Scully et al. 2000).

In some species, hairs associated with scent glands may retain and disperse glandular secretions. In Chapin's Free-tailed Bat, *Chaerephon chapini* (Molossidae), males possess a tuft of conspicuous hairs on their head, more prominent during reproductive seasons, that disperse scents produced by a gland at its base. Male Yellow-shouldered Bats, *Sturnira* spp. (Phyllostomidae), have shoulder glands associated with specialized shoulder hairs that retain and disperse glandular secretions, giving these bats their characteristic shoulder spots (Fig. 4).

A different strategy is seen on Sac-winged bats (Emballonuridae) that have sacs on their

**Microchiroptera Life History, Fig. 3** Visored Bats (*Sphaeronycteris toxophyllum*), a sexually dimorphic microbat. (a) Female and (b) Male. Note the size difference of the fleshy protuberance in their faces. (Author: Guilherme Garbino)

**Microchiroptera Life History, Fig. 4** Male (a) and female (b) Little Yellow-shouldered Bat (*Sturnira lilium*) captured during the reproductive season. Note the

conspicuous spots in the male's shoulder, where glands are associated with hairs that retain and disperse glandular secretions. (Author: Fred Victor de Oliveira)

propatagium and/or uropatagium, which do not have a glandular function but acts as fermentation chambers instead. In these sacs (less pronounced in females), males store and ferment saliva, urine, and other body secretions to produce scents. Males spread the scent during hovering flights to mark their roost surfaces and even females of its harem. This behavior, in addition to visual and vocal displays, serves to attract females and also to repel rival males (McCracken and Wilkinson 2000; Scully et al. 2000).

## Reproduction

Most bat species reproduce seasonally, and the timing is determined by climate and periods of optimal food availability. Reproduction is timed to ensure that lactation (or weaning in some species) occurs at the same time as the peak of food available (Racey 1982; Racey and Entwistle 2000). Bats from more stable environments where food sources fluctuate less throughout the year (as in tropical forests) may have aseasonal reproductive patterns. On the other hand, bats from regions where food supplies vary markedly throughout the year show pronounced seasonality in reproduction and may reproduce only during

periods of maximum food availability (Racey 1982; Racey and Entwistle 2000).

The reproductive activity of some species (insectivorous and frugivorous) in tropical environments may be associated with rainfall seasons (when food availability reaches its peak). Contrasting to sympatric bats of different feeding habits, reproduction of nectarivorous species, however, may mirror the flowering of plants, and females may give birth during the dry season instead (Racey and Entwistle 2000). In temperate zones, where climate varies markedly between winter and summer, the reproductive activity of bats is constrained by climate and food availability, since most species are insectivorous and insect availability reaches its peak during summer. Bats that inhabit seasonal environments but rely on stable food resources, such as vampire bats, may also be able to reproduce year-round (Racey and Entwistle 2000). The timing of male reproduction may also correspond with climatic and food seasonality. At temperate latitudes, spermatogenesis corresponds with the peak of insect availability, and in tropical species, it corresponds to rainfall season with high food availability (Racey and Entwistle 2000) (Fig. 5).

There are many reproductive patterns reported for microbats. Temperate species (mostly

**Microchiroptera Life History, Fig. 5** Male Pale Spear-nosed Bat (*Phyllostomus discolor*). In many tropical species, spermatogenesis occurs during rainfall seasons, when food availability reaches its peak (note the conspicuous testicles). (Author: Fred Victor de Oliveira)

Horseshoe Bats (Rhinolophidae) and Vesper Bats (Vespertilionidae) have seasonal monoestry, where females have a single litter during one specific climatic season. (Racey and Entwistle 2000). However, in tropical species, there are at least ten different patterns that range from restricted seasonal monoestry (e.g., *Nycteris thebaica* (Nycteridae)) to aseasonal polyoestry (e.g., *Molossus ater*, *Chaerephon pumilus* (= *Tadarida pumila*) (Molossidae)). Aseasonal polyoestrous species have a variable number of litters per year, and females estrous is not synchronized, hence young are born throughout the year instead of in a single climatic season (Happold and Happold 1990; Racey and Entwistle 2000). The cycles of males and females may also be synchronized; males may have a single peak of spermatogenesis when females are monoestrous, two peaks when females are dioestrous, and an extended period of spermatogenesis or be fertile the whole year when females are polyoestrous or aseasonal breeders (Racey and Entwistle 2000).

As in other mammals, during copulation, males will transfer sperm to fertilize the egg released by females during ovulation. In some species, males may store sperm after spermatogenesis and, after mating, females may store

**Microchiroptera Life History, Fig. 6** A pregnant Riparian Myotis (*Myotis riparius*). (Author: Nathália Louzada)

viable sperm within their tracts for even periods of several months (Crichton 2000). Most sperm-storing species are seasonal breeders from temperate regions, where their reproductive cycle is interrupted by hibernation. The sperm stored by hibernating species retains its viability through the course of the hibernal period (for up to 10 months), and some nonhibernating tropical species may also store sperm. Sperm storage is reported in the families Rhinolophidae, Vespertilionidae, Miniopteridae, and Molossidae, but it may also occur in other families such as Rhinopomatidae and Emballonuridae (Crichton 2000; Racey and Entwistle 2000).

The cells will start to divide after fertilization, and the process of implantation connects the embryo to the circulatory system of its mother, which will provide nutrient and oxygen support and the removal of metabolic wastes. Embryo implantation may occur a few days after fertilization (e.g., Vespertilionidae) up to almost 2 weeks (e.g., Noctilionidae) (Fenton and Simmons 2014). If fertilization and implantation take place correctly, the female will then be pregnant (Fig. 6).

Pregnancy in bats is considered long for mammals of their size. Gestation length varies among species but also within a single species due to developmental delays (Fenton and Simmons 2014; Badwaik and Rasweiler 2000). Female bats from temperate latitudes (Rhinolophidae

and Vespertilionidae) and some species in the tropics (e.g., Miniopteridae and Phyllostomidae) display some form of delay in their reproductive cycle. They are capable of delaying ovulation, fertilization, implantation, and even the development of embryos (Racey 1982; Racey and Entwistle 2000). These strategies, and also sperm storage, are used to ensure that the timing of birth coincides with the season of optimal resources for lactation and growth of newborns.

Embryo development is delayed in temperate species once bats enter torpor or hibernation, but, in tropical/subtropical species, delays may occur by alternative mechanisms (Tuttle and Stevenson 1982). In light of these circumstances, lengths of gestation range widely among microbats, from circa of 40 days up to 11 months (Tuttle and Stevenson 1982).

Female bats give birth to large pups, and the average body mass of the neonatal microbat is more than 20% of the maternal body mass. Horse-shoe Bats (Rhinolophidae) have the highest neonatal body mass among microbats, and newborns weight an average of 28.8% of their mother's body mass (Kurta and Kunz 1987). Despite their relatively large size at birth, young microbats are functionally altricial: most species are born naked, with eyes closed, have limited thermoregulatory abilities, and are dependent on their mothers for nutrition (Kurta and Kunz 1987; Kunz and Hood 2000) (See [Thermoregulation Challenges and Postnatal Growth](#)).

Most bat species give birth to a single offspring per pregnancy, and few species frequently produce twins (e.g. *Eptesicus fuscus*) (Fig. 7). However, bats from the genus *Lasiurus* (Vespertilionidae) have the largest litter sizes among Chiroptera and give birth up to four offsprings per gestation. While bats from temperate latitudes tend to have a single reproductive event within a year, many species from less constraining environments (tropical regions) increase their reproductive potential by exhibiting postpartum oestrus, hence increasing the number of offsprings they can produce in a year (Badwaik and Rasweiler 2000; Racey and Entwistle 2000). Some species, as the Indian Pigmy Bat, *Pipistrellus tenuis* (= *Pipistrellus mimus*) (Vespertilionidae), constantly produce

**Microchiroptera Life History, Fig. 7** A male and two females Seba's Short-tailed Bat (*Carollia perspicillata*), each with its offspring. (Author: Daniele Pedrosa)

twins and can give birth up to six young within a year (Suthakar Isaac et al. 1994)

## Lactation and Parental Care

After pups are born, the female microbats provide parental care until weaning age, in the form of nutritional and non-nutritional forms of care. Non-nutritional care includes protection, sensory stimulation, thermal influence, pup retrieval and transport, while nutritional care involves lactation and provision of other food supplies for the young (Kunz 1982; Kunz and Hood 2000).

Female bats possess a pair of mammary glands and nipples located close to their armpit, which serves to feed milk to the young (Fig. 8). In *Lasiurus* spp. and *Otonycteris* spp. (Vespertilionidae), however, there is an additional pair of nipples (Simmons 1993). In the Thumbless Bat, *Furipterus horrens* (Furipteridae), the pair of nipples is located in the abdominal region, just above the genitalia, unlike all other chiropterans (Uieda et al. 1980).

Juveniles also use nipples as an attachment point to their mother's body (Fig. 9). In some species, females also possess an additional pair of pubic nipples to serve as anchoring points. Pubic nipples are present on females of several families of microbats: Craseonycteridae, Hipposideridae, Megadermatidae, Rhinolophidae,

**Microchiroptera Life History, Fig. 8** The nipple of a lactating female Seba's Short-tailed Bat (*Carollia perspicillata*). (Author: Nathália Louzada)

**Microchiroptera Life History, Fig. 9** A female Seba's Short-tailed Bat (*Carollia perspicillata*) hanging upside down with its young attached. (Author: Daniele Pedrosa)

lactating purposes, they are associated with lacteal tissue in at least some species of Rhinolophid, Hipposiderid, and Rhinopomatid bats (Simmons 1993). Pubic nipples are polymorphic for males in some species, where they can be present or absent.

In many species, juvenile bats may remain attached to its mother almost continuously, have multiple suckling events, and females even transport them while foraging (e.g., many New World Leaf-nosed Bats (Phyllostomidae)). This behavior is uncommon in other species (mostly small insectivores), where young are not constantly attached to their mothers, and suckling events are not frequent. In these species, females leave their offsprings at roosting sites when emerging to forage and feed them after returning and later on a regular schedule (Kunz and Hood 2000). When foraging, some females often leave their young at sites that are different from their day roosts (e.g., Slit-faced Bats (Nycterids) (Fenton and Simmons 2014)).

Most females only allow pups to suckle if recognized as their young. Nursing mothers roosting in large colonies may rely on spatial memory, acoustic, tactile, olfactory, and visual clues to distinguish their offspring from others (Kunz and Hood 2000) (Fig. 10). Some pups may try to steal milk from unrelated females and, in some species, females sometimes nurse unrelated offsprings as they approach weaning age (e.g., *Nycticeius humeralis*) (Kunz and Hood 2000).

Young bats use milk teeth (deciduous teeth) shaped like small hooks to attach to their mothers. This shape is unique among mammals, where milk teeth usually have form and function similar to permanent teeth that replace them later. In bats, permanent teeth are different in shape, size, and function from milk teeth and the number and form of permanent teeth vary from species to species and are also related to feeding habits. Vampire Bats (*Desmodus rotundus*, *Diphylla ecaudata*, and *Diaemus youngi* (Phyllostomidae)), for example, use large blade-shaped incisors to cut through the skin of their prey to access blood. On the other hand, their molars and premolars are small, simplified in shape, and reduced in number because these bats do not need to chew their food.

Rhinonycteridae, and Rhinopomatidae (Simmons 1993). Although pubic nipples do not serve for

### Microchiroptera Life

**History, Fig. 10** A female mustached-bat (*Pteronotus rubiginosus*) roosting with multiple young. Females rely on spatial memory and sensory clues to recognize their offspring among others. (Author: Daniele Pedrosa)

Females undoubtedly play the major role in raising the juvenile, and paternal care is rare among bats in general. Direct evidence of paternal care comes from monogamic species where males defend territories where young bats learn to feed, and offsprings remain with their parents for an extended period (Kunz and Hood 2000). In Yellow-winged Bats, *Lavia frons* (Megadermatidae), the juvenile remains with its parents for up to 50 days after learning to fly. Spectral Bats, *Vampyrus spectrum* (Phyllostomidae), are carnivorous bats that live in pairs or extended small groups with their newborn and an older offspring. Both parents and older offspring take care of the young, and at least one bat stays in the roost with the juvenile while the others forage. The foraging bats bring prey back to the roosting site, provisioning food to both young and the bat that remained in the roost (Kunz and Hood 2000; McCracken and Wilkinson 2000; Altringham and Senior 2005).

In most species from temperate zones, males assume little to no responsibility in parenting, since maternity roosts comprises mainly nursing females and their offspring. In contrast, males from tropical zones may display some form of parental care when constructing tents for roosting (e.g., many fruit-eating phyllostomids), defending roosting sites and groups of pregnant and lactating females from other males and predators (Kunz and Hood 2000; McCracken and Wilkinson 2000).

The weaning age differs from species to species; less than 3 weeks in small vespertilionids to over 7–9 months in the Common Vampire Bat (*Desmodus rotundus*) (Fenton and Simmons 2014). At the onset of weaning, mothers and young of several species are reported flying and even foraging together (Kunz and Hood 2000). After weaning, the age of reproductive maturity is highly variable among species, between males and females of the same species and even between same-sex individuals of a single species (Tuttle and Stevenson 1982).

Most bats reach sexual maturity at 1 or 2 years of age, but some species only in few months (e.g., 3 or 4 months in some vespertilionids) (Racey 1982; Tuttle and Stevenson 1982). However, the onset of reproductive maturity is delayed even further in some species such as the Lesser Horseshoe Bat, *Rhinolophus hipposideros* (Rhinolophidae), where some females may give birth to their first young at 3–7 years of age (Racey 1982).

### Age Estimation

Estimating the age of a bat can be difficult, because, when it reaches adulthood, there are few ways to differentiate age classes. In some well-known species, juveniles and adults are distinguished by the length of long bones with linear growth rates, such as forearm, metacarpals, and

digits (Brunet-Rossini and Wilkinson 2009). However, a common way to tell apart young bats from subadults and adults is by looking at the closing patterns in the epiphyseal growth plates of their phalanges. In very young bats, the tissue on their epiphyseal plates is less mineralized, and the epiphyseal plates eventually close as the bat grows, until they are fully fused. In many species, juveniles' pelage is usually darker, less dense, and thinner from that seen in adults, and only after the first molt it will have the same aspect as the adult's fur (Brunet-Rossini and Wilkinson 2009).

### Thermoregulation Challenges and Postnatal Growth

The increased surface area of bats' wings leads to passive thermal conductance when flying and roosting, which increases the energetic demands of thermoregulation (Ochoa and Kunz 1999). Bats can minimize thermoregulation costs by selecting roosts that approach thermal neutrality and clustering.

Clustering modifies the microclimate of the environment because a large number of bats roosting within the same site increases local ambient temperature (Altringham and Senior 2005). In the Neotropics, some cave-dwelling bats roost in large aggregations of hundreds of thousands of individuals in subterranean chambers called hot caves. This term is applied to caves with constant

high ambient temperatures that are caused by body heat emanating from the high bat density, and also from decomposing guano (some caves can reach approximately 40° C) (Ladle et al. 2012). Mustached Bats (Mormoopidae) are the main species associated with Hot Caves, and many mormoopids and some Funnel-eared Bats (Natalidae) have limited geographic ranges or are restricted to hot caves environments year-round or during parturition (Ladle et al. 2012).

Since young bats are born altricial and have limited ability to regulate their body temperature, thermal conditions also play a role in their development (Racey and Entwistle 2000; Kunz and Hood 2000). Mothers help maintain the body temperature of their young sharing body heat through conduction and radiation, and warmer roost temperatures enhance young survival and promote rapid pre- and postnatal growth (Racey 1982; Racey and Entwistle 2000; Kunz and Hood 2000). In many species, females form maternity colonies, and the dense clustering of juveniles assists in heat exchange (e.g., mormoopids, molossids, some nectar-feeding phyllostomids) (Fig. 11).

### Torpor and Hibernation

For bats from temperate regions, it is difficult to remain active year-long and maintain endothermy because cold temperatures demand an increased

**Microchiroptera Life History, Fig. 11** A maternity colony of the mustached-bat (*Pteronotus rubiginosus*). Young bats have limited ability to regulate their body temperature, and clustering assists in heat exchange. (Author: Daniele Pedrosa)

rate of heat production and food consumption (McNab 1982). The majority of temperate species are insectivorous, and besides colder temperatures, they also face a shortage of food availability during winter. Frugivorous and insectivorous bats only enter marginally in temperate latitudes and do not face the same challenges as insectivorous species, which are widely distributed in temperate zones (McNab 1982).

To avoid or minimize changes in climate and food resources, temperate bats must migrate to warm climates to retain endothermy or enter in torpor/hibernation for extended periods. Although tropical species do not hibernate, some may enter torpor when temperatures are too low.

Bats achieve torpor lowering their body temperature to ambient levels (as long as the ambient temperature does not approach to or fall below freezing) and lowering their metabolic rates to reduce their daily energy requirements (Racey and Entwistle 2000; Kunz and Hood 2000). During hibernation, bats spend much or all winter in extended periods of torpor, and the length of these periods vary in response to environmental conditions, body size, and species (torpid periods are longer at low temperatures and small-bodied species) (McNab 1982).

Although there is reduced rate of metabolism and energy expenditure, long hibernal periods require significant amounts of energy that is provided by fat accumulated before hibernation (Fleming 2019). During hibernation, bats may still show some levels of activity that is influenced by temperature, clustering behavior (if they hibernate alone or in clusters), energetic demands, and species (McNab 1982). Hibernation is also closely associated with reproduction in temperate bats; mating occurs before or during hibernal periods, sperm is stored, delayed reproductive processes (ovulation, fertilization, implantation, and gestation), and parturition and lactation occur after the end of hibernation.

## Migration

Migration is an essential feature on the life history of many microbats, and species migrate to deal

with seasonal changes in climate, food availability, and also to find hibernation or nursery roosts (Altringham and Senior 2005; Fleming 2019). Unlike birds, bats are relatively short-distance migrants, and intercontinental migration is uncommon (Fleming 2019).

Many bats from temperate and subtropical zones are migratory. In temperate species migration and hibernation are closely associated, and bats may migrate and/or hibernate to overcome a seasonal shortage of food resources during winter when the energetic demands of homeothermy increase (Altringham and Senior 2005). These species accumulate fat before or during migration, which will provide energy later during hibernation.

Among temperate bats, there are a variety of migratory behaviors: (1) nonmigratory species that breed and hibernate within a 50-km radius or less (e.g., *Rhinolophus* spp., *Corynorhinus rafinesquii*), (2) regional migrants that migrate 100–500 km between seasonal roosts (e.g., *Myotis* spp., *Perimyotis subflavus*), and (3) long-distance migrants, which migrate 1000 km or more between seasonal roosts (e.g., *Lasionycteris noctivagans*, *Nyctalus* spp.) (Fleming 2019). Migration may also not apply to all individuals in some species, and while some populations are sedentary, others are migratory (*Vespertilio murinus*, *Tadarida brasiliensis*) (Fleming 2019).

Bats from temperate zones may form swarms during late summer when hundreds of thousand bats visit roosts that are used for hibernation later during winter (Altringham and Senior 2005). Throughout the swarming season, bats from different populations may fly to the same sites to mate (which can reduce inbreeding), and this behavior may also act as an introduction of hibernation sites for young bats born early in the year (Fenton and Simmons 2014).

Migration is less common among tropical and subtropical species, and, when present, is not associated with hibernation but with food gradients or seasonal food resources instead (Fleming 2019). The Lesser Long-nosed Bat, *Leptonycteris yerbabuenae* (Phyllostomidae), for example, is a nectarivorous, long-distance migrant species that migrate following a “nectar corridor” of flowering

columnar cacti in Mexico and southeastern United States of America (Fleming 2019).

Sex-biased migrations and seasonal spatial segregation occur in some temperate and tropical/subtropical migrant species, and males and females may differ in the distance each sex migrates and also to where they migrate. For example, during summer, male Hoary bats, *Lasiurus cinereus* (Vespertilionidae), are found in western North America while females are in north-central and northeastern United States and Canada (Fleming 2019). Females tend to be more migratory than males and migrate long distances to find nursery roosts where their maternity colonies are formed (see [Thermoregulation Challenges and Postnatal Growth](#)) (Altringham and Senior 2005; Fleming 2019).

## Lifespan

The lifespan of microbats is, on average, at least three times greater than nonflying mammals of similar size (Wilkinson and South 2002). Data on the longevity of microbats are scarce, and most come from studies with banded animals recaptured over the years in the wild (Fig. 12). Greater Horseshoe Bat, *Rhinolophus ferrumequinum* (Rhinolophidae) and some vespertilionids (*Myotis* spp., *Plecotus* spp.) are known to live more than 30 years, while one specimen of Brandt's Myotis, *Myotis brandtii* (Vespertilionidae), is known to live at least 44 years after its banding (Fenton and Simmons 2014).

Hibernation seems to be involved in the extended longevity of bats, since it allows them to escape severe weather conditions and food shortages, thereby delaying physiological deterioration (Brunet-Rossini and Wilkinson 2009). Several hibernating species have lifespan 6 years longer than that of species that do not hibernate when comparing the average maximum lifespans of microbats (Wilkinson and South 2002). Bats live long and have a low mortality rate relative to their body size. Flight and the use of protected roosts may reduce extrinsic mortality, providing secure shelters and agility to avoid and

**Microchiroptera Life History, Fig. 12** Banding of a Flat-faced Fruit-eating Bat (*Artibeus planirostris*). Banded animals help scientists keep track of their movement and life history throughout the years. (Author: Fred Victor de Oliveira)

escape predators (Kunz 1982; McCracken and Wilkinson 2000).

## Conclusion

Bats, in general, are a diverse group of mammals, which reflect in the variety of natural histories and life histories found among the order Chiroptera. Bats' life history includes a range of social systems, mating systems, spatial behaviors, reproduction strategies, and tactics to overcome environmental challenges. Despite such diversity and complexity of known and unknown life histories, all bats must find ways to grow, reproduce, and survive in their own environment.

e Biologia Evolutiva, Instituto de Biologia,  
Universidade Federal do Rio de Janeiro, Rio de  
Janeiro, Brazil

### Introduction

The name “Chiroptera,” derived from the Greek words *cheir* (=hand) and *pteron* (=wing), refers to the hand-like wings of bats, feature related to their unique ability, among all mammals, to perform true flights. Flight confers bats the access to exclusive resources (food, places to roost), not available to animals that walk, run, burrow, or climb; helps them to avoid and escape from potential predators; and gives them a higher mobility that allows some species to migrate long distances. Part of their diversity success (c.a. 1300 species), being the second largest order of mammals, is attributed to that (Fenton and Simmons 2014). The forearm (radius and ulna), metacarpals, and fingers of bats are elongated, and, with the patagium, they form the strong structure of the wing (Neuweiler 2000). The wing morphology varies among taxa and can be associated to different ecological guilds and flight patterns (Norberg and Rayner 1987). Despite these incredible modifications associated to flight, some bats have also a great ability to crawl, performing several movements on the ground (Schutt and Simmons 2006).

The traditional suborder Microchiroptera (=echolocating bats) is not recognized nowadays, because evolutionary studies have shown that some “microbats” (e.g., Rhinolophoidea) are more closely related to “megabats” (Fenton and Simmons 2014). Currently, bats are classified in suborders Yangochiroptera and Yinpterochiroptera (Amador et al. 2016). In this sense, the expression “microbats” includes representative of both currently recognized suborders. An efficient aerial locomotion is present in all taxa,

but the quadrupedal one has evolved independently in some lineages of Yangochiroptera (Riskin et al. 2016). A detailed review of aerial and quadrupedal locomotion of bats is made below.

### Aerial Locomotion

#### The Wing Structure and Morphology

The wing of a bat (Fig. 1) consists of the same elements of the mammalian forelimb but has passed through some modifications: the humerus is large, strong, and suspended from the scapula; the arm is elongated and consists of two bones, the sturdy radius and the thin ulna; the hands include six carpals, five metacarpals, and five sets of phalanges. The first metacarpal, or thumb, is the only digit with a functional claw in extant “microbats” and retains its functions as a freely moving grasping tool. The second to fifth metacarpals are greatly elongated and form a supporting structure to the wing membrane. The wing membrane, or patagium, is very thin and almost lacks a fur cover; it is stretched between the side of the body and the arm (plagiopatagium), between the fifth finger and the wing tip (chiropatagium), between the shoulder and wrist (propatagium), and between the legs and the tail (uropatagium). The patagium have several intrinsic muscles, and fibers of several muscles pass into it (e.g., *coraco-cutaneus*, *humeropatagialis*, *tensor plagiopatagii*). The plagiopatagium and propatagium support the weight of the body during flight; the chiropatagium functions mainly to propel the bat forward; and the uropatagium acts during horizontal takeoffs and very slow flight by producing important thrust and also aids in complicated maneuvers of aerial insectivorous bats (Vaughan 1966; Neuweiler 2000; Gardiner et al. 2011; Adams et al. 2012).

The patterns of flight in bats depend partially on the size and form of the wings (Fig. 2). For this reason, the morphology of the wings provides an evidence about bats’ preferred flight style and foraging strategies, and flight performance indices can be inferred from wing measures of the

**Microchiroptera**

**Locomotion, Fig. 1** Wing profile of *Gardnerycteris crenulatum* (Phyllostomidae) showing the modified bones and patagium that constitute the wing. Note the large forearm and elongated digits (Dig. II to Dig. V) and the membranes that are stretched between the hands, the leg bones, and the body. (Figure: Nathália Siqueira Verissimo Louzada)

species – wingspan (B), wing area (S), length of the hand-wing (lhw), length of the arm-wing (law), hand-wing area (Shw), and arm-wing area (Saw) – plus the body mass. The main indices are the wing loading (WL), which is the specimen's weight divided by the wing area ( $Mg/S$ ) and is related to the mean pressure on the wings, and the aspect ratio (AR), which is the square of the wingspan divided by the wing area ( $B^2/S$ ), and correspond with aerodynamic efficiency and energy losses in flight. Additional indices are the tip length ratio ( $TL = lhw/law$ ), related to maneuverability, tip area ratio ( $Ts = Shw/Saw$ ), and tip shape index ( $I = TS / (TL - Ts)$ ) (Norberg and Rayner 1987; Neuweiler 2000).

The wings of bats can vary from narrow to wide and long to short (Fig. 2). Narrow wings usually have small wing area and high wing loadings, and the bat with this morphology must fly fast to obtain sufficient weight to support (e.g., Molossidae). Bats with long wings (high wingspan) of high aspect ratio usually have low or average wing loading and fly slowly (e.g., Mormoopidae, Vespertilionidae), which should be advantageous by migratory bats, whose goal is to minimize the energy consumed covering a given distance. Bats with short, broad wings (low aspect ratio) and large wing area (low wing loading) can fly slowly within vegetation (e.g.,

Phyllostomidae). The size and shape of the uropatagium also vary, from reduced (e.g., *Sturnira*, *Desmodus*) to well-developed, and may completely enclose the tail (e.g., Vespertilionidae) or just a part of it (e.g., Molossidae). The presence of a well-developed tail membrane may contribute to lift and to help on the stabilization of the body during turns and other maneuvers when bats are flying (Norberg and Rayner 1987; Neuweiler 2000; Feldhamer et al. 2007).

The wing morphology and flight are also correlated to the use of the space (open, edge, and narrow) and the functional guilds that bats occupy (Table 1). Open space foragers have a wing adapted for fast aerial-hawking flight – they have high aspect ratio and pointed wings. Edge space foragers have a slow and maneuverable flight with low cost – they have average aspect ratios, average wing loadings, and rounded wing tips. In this category are the trawling foragers, with long wings, average wing loading, and high aspect ratio, which allow them to forage above water surface with an economic flight. Narrow space bats have short and broad wings, with rounded wing tips, that give them high maneuverability in confined spaces – the aspect ratio and wing loading are low (Norberg and Rayner 1987; Kalko et al. 1996; Denzinger and Schnitzler 2013).

**Microchiroptera Locomotion, Fig. 2** Wing profile of species of bats representative of Phyllostomidae ((A) *Trachops cirrhosus*, (B) *Carollia perspicillata*, (C) *Sturnira lilium*, (D) *Desmodus rotundus*), Vespertilionidae ((E) *Myotis nigricans*), and Molossidae ((F) *Molossus rufus*). Note the variation from wider (A–D) to narrower (E, F) wings; the aspect ratio increases as wings become longer and thinner, while the wing loading increases as wings become wider. Note the variation in the

uropatagium shape and the tail development: in *Sturnira* (C) and *Desmodus* (D), the uropatagium is poorly developed, and the tail is absent; in *Trachops* (A) and *Carollia* (B), the uropatagium is well-developed, with a notch in *Carollia*; and in *Myotis* (E) and *Molossus* (F), the uropatagium is developed, in V-shape, but the tail in *Myotis* is enclosed on the membrane, while in *Molossus* its distal part is free. Scale bar: 1 cm. (Figure: Nathália Siqueira Veríssimo Louzada)

**Microchiroptera Locomotion, Table 1** Flight characteristics of families of bats. Due to great morphological diversity of Phyllostomidae, their subfamilies are

considered separately. (Data from Norberg and Rayner (1987), Kalko et al. (1996), and Marinello and Bernard (2014). ND: no data available on literature)

## Aerodynamics

Flight requires production of two forces combined that allow a bat to rise, to fly at a constant speed and elevation, and to move forward through the air – the lift, a vertical force that counterbalance the bat’s mass, and the thrust (propulsion), a horizontal force that counterbalance the drag (resistance of the body and wing), both produced by the wingbeat (Neuweiler 2000; Fenton and Simmons 2014). The air traveling across the upper surface of the wing moves faster than in the lower surface, which result in lower air pressure above the wing, sucking the wing upward and higher pressure below the wing, pushing the wing up. These different pressures – high under the wing and low above – generate lift. The thrust is provided by the movement of the air across the top of the wing, producing vortices that generate most of the aerodynamic force required to propulsion (Neuweiler 2000; Fenton and Simmons 2014).

While flying, bats continuously change the position of their body and limbs and adjust the position of the wings by the flexion and extension

of the structures that support them (e.g., arm and hand bones, hind limbs, thumbs, calcar), dynamics that are critical to produce changes in flight direction. The lift and the thrust are influenced by the curvature of the airfoil and their angle of attack – if the angle is too shallow, the less lift is produced, and if is too steep, stalling may occur (Fenton and Simmons 2014). The airfoil section of the wings in bats is located between the body and the fifth finger, and this finger can be stretched causing the entire wing membrane to curve upward, adjusting the camber of the wing. A steeper angle of attack is produced by an adjustable leading-edge flap in the propatagium that is made through movements of the thumb – when the bat is flying slowly or executing difficult maneuvers, the angle of propatagium is increased, thereby improving lift (Neuweiler 2000; Fenton and Simmons 2014).

The speed that bats can reach during flight depends on the species and the situation – bats hunting flying insects, for example, have flight speeds between 10 and 34 kph (e.g., 18 kph in *Myotis lucifugus*, 34 kph in *Tadarida*

*brasiliensis*), while migrating bats can approach over 50 kph (e.g., *Lasionycteris noctivagans*). Bats flying over water, however, adjust their wingbeats and move more slowly (8 kph). The metabolic rate and relative costs of different activities of bats are dynamic – a bat (e.g., *Myotis lucifugus*) hibernating has a pulse about 5 beats per minute (bpm), while a bat hanging in a roost has about 200 heartbeats per minute, and a bat flying over an insect has 1000 bpm (Fenton and Simmons 2014).

When a bat is flying straight ahead in a horizontal course, both wings move forward at the same time, from about 60° above the long axis of the body to about 30° below, and, to stay airborne, they require 8–15 wingbeats/s. The wing tips have a propeller-like action, describing a path shaped like a figure eight during each wingbeat cycle. During the upstroke, the surface of the wing is reduced to about 65% of its full size – the chiroptagium remains fully outstretched, while other wing surfaces are slightly bent. The downstroke is primarily responsible for generating lift and takes up 50–60% of the wingbeat cycle. To achieve fast speeds, the amplitude of the wingbeat is reduced, and the wings are sustained almost passively by the air pressure under the wing membranes, saving energy by maintaining airborne as long as possible. This type of flight would be important to migration bats, which can travel the longest possible distance using a limited energy supply (Neuweiler 2000; Fenton and Simmons 2014). When a bat hovers, there is no horizontal propulsion to provide the air flow through the wing (the flight speed is zero), and the air flow must be generated by the wingbeat. Thereby, this flight consumes a great deal of energy and can only be maintained for short periods of time. Bats with short, broad wings, such as nectarivorous bats (*Glossophaga soricina*; Phyllostomidae), are best suited for this type of flight, using the upstroke to generate lift – the plagiopatagium remains folded to reduce air resistance, while the chiroptagium is extended and supinated, and the wings are raised high relative to the body so that they beat in a forward direction rather than a downward one, which generates lift rather than

thrust, thus keeping airborne (Neuweiler 2000; Fenton and Simmons 2014).

The takeoff and flight of bats are facilitated by their elevated hanging upside-down position in twigs or ceilings of caves, which means that “taking off only involves letting go and spreading your wings – gravity does the rest” (Fenton and Simmons 2014). This posture does not require any energy, due the presence of unique tendons and tendons sheaths that allow their feet to lock closed when the bat is roosting. In this means, the legs of bats are considered to serve mainly as a framework to support the wing membranes during flight and thus are small, thin, and not very muscular (Neuweiler 2000; Fenton and Simmons 2014). Some recent studies, however, have been demonstrating that this is not true for all bats. Louzada et al. (2019), for example, showed that the femurs of bats that have functional demands associated to an active use of the legs (e.g., in quadrupedal and trawling behavior) are more robust than the femurs of bats that do not present such functional demands. Similar patterns can be observed in other structures of the bat’s legs (Celeita et al. 2018), and the reduction of the hind legs is not seen in all lineages (see section “[Quadrupedal Locomotion](#)”).

### **Skeleton and Musculature Adaptations to Flight**

The skeleton of bats comprises several morphological specializations associated to an efficient flight. The manubrium, the first two ribs, and the last cervical and first two thoracic vertebrae are fused and form the pectoral ring, which anchor the wings. The column is rigid, with the thoracic vertebrae tightly connected to one another, the sternum presents a keel for the insertion of strong pectoral muscles, the clavícula is robust, and the scapula is parallel to the vertebral column, holding the muscles that controls the wingbeat cycle during flight. The rib cage is large and often broader than deep, and the cervical vertebrae are twisted so the bat’s head can stand raised during flight. The ilium and the sacrum are fused together up to the level of the acetabulum, limiting the mobility at the iliosacral joint and producing stability during flight. The shape of the bone of the upper arm

(humerus) and shoulder blade (scapula) shows great diversity among bats and probably reflects differences in their flight abilities (Vaughan 1970; Neuweiler 2000; Feldhamer et al. 2007; Fenton and Simmons 2014).

There are nine pairs of muscles involved in powering flight of bats. The wingbeat is provided by elevator and depressor muscles (located on the back and on the chest, respectively), most of them acting to adjust the position of the wing and a few more powerful being responsible for the wingbeat itself. This gives the bats agility and maneuverability that could never be achieved by birds, which have just two pairs of muscles (“elevator” and “depressor”) to control wingbeat. The thin profile of the chest observed in bats, when compared to birds, given by the attachment of the musculature both in back and front, probably allowed them to squeeze into crevices and through small openings, facilitating the access to exclusive roosts. Bats also have at least five exclusive muscles associated to the control of the wing membranes: the *m. occipito-pollicalis*, which pulls the propatagium and increases the area of camber of the plagiopatagium; the *m. coraco-cutaneus*, which anchors the elastic fibers of the plagiopatagium to the axilla, helping to reinforce this membrane; the *m. depressor ossis styloformis*, which spreads the uropatagium by pulling the calcar laterally; the *humeroptagialis*, which tightens and braces the distal parts of the wings membrane; and the *m. tensor plagiopatagii*, which strengthens the connection between the plagiopatagium and the lower leg and helps maintain the tautness of the posterior part of the plagiopatagium when the wings are spread (Vaughan 1959; Neuweiler 2000; Fenton and Simmons 2014).

The set of muscles that act during flight varies in the downstroke and in the upstroke of the wing. During the downstroke, the muscles that act in the most control are *pectoralis*, *serratus*, and *clavodeltoideus*. The last two are supporting muscles, acting on the ribs and scapula, and the first one, *pectoralis*, is originated on the sternum and is inserted on the humerus, providing the main power for the downstroke and, in some bats (e.g., *Eumops*), weighting four times as much as

the next largest muscle, the *serratus*. The adjustments of the angle of the wing according to different flight conditions are also made by *m. pectoralis*. Their contraction pulls the wing downward and forward, and, depending on which part contracts more strongly, the humerus may assume different rotational positions. Another important muscle to the downstroke is the *subscapularis*, which controls the position of the wing during rotational movements (Vaughan 1959, 1970; Neuweiler 2000).

Regarding the upstroke of the wing, four muscle groups accomplish the action, the *rhomboideus*, the *trapezius*, the *deltoideus*, and the *serratus*. The first two act pulling the shoulder blade across the torso in the direction of the spine, the third one lifts and rotates the humerus, and the last one provides fine control at the beginning of the upstroke. Usually, little force is required for upstroke because the air pressure under the wing surface passively forces it upward. For reverse the wing direction, however, it requires more energy than any other phase of flight, and several muscles need to act, mainly the *latissimus dorsi* and the *infraspinatus*. In general, the flight muscles of bats are adapted for the metabolism of fatty acids rather than glycogen, which contributes to reduce the weight during flight – fat reserves contain eight times as much energy as a glycogen reserve of equal weight (Vaughan 1959, 1970; Neuweiler 2000).

## Quadrupedal Locomotion

The quadrupedal ability has evolved independently in three lineages of Yangochiroptera: in Desmodontinae (family Phyllostomidae), which occurs in Central and South America and is represented by three species, *Desmodus rotundus*, *Diaemus youngii*, and *Diphylla ecaudata*, all hematophagous; in Mystacinidae, represented by a single living species, *Mystacina tuberculata*, omnivorous and endemic from New Zealand; and in Molossidae, represented by 17 genera and more than 100 insectivorous species with pantropical distribution (Gregorin and Cirranello 2015;

Amador et al. 2016). In Desmodontinae, the quadrupedal locomotion is employed to approach the food resource – blood of mammals or birds; in Mystacinidae, it is used to forage on the forest floor, searching for flowers, fruit, and soil insects. In Molossidae, on the other hand, this habit is associated with roosting behavior, allowing them to access narrow spaces in rocks, trees, roofs, or hollows, and facilitating movement within these locations. As a common strategy, all groups can use the quadrupedal habit to avoid possible threats (predators) during roosting and foraging behaviors (Schutt and Simmons 2006; Riskin et al. 2016).

### Morphological Adaptations in Quadrupedal Bats

The quadrupedalism is a consequence of a series of changes in both the appendicular skeleton and the external morphology of these groups. Externally, these bats have modifications that help and increase contact with the surfaces on which they walk, including metacarpal pads, developed thumbs, reduced calcaneus and uropatagium, in Desmodontinae; lateral pockets in the body where the wing tips are inserted, secondary claws at the base of the thumb and foot, and adhesive discs in *Mystacina*; and lateral pockets, spatulate bristles on digit I of the foot, and inclination of the thumb relative to the other digits, in Molossidae (Schutt and Simmons 2006).

The position of the hind limbs, anterolaterally oriented in specialized quadrupeds, appears to be determinant to the quadrupedal ability – the femur is directed anterolaterally and the tibia vertically, allowing greater and more efficient limb mobility during terrestrial locomotion. The lower limbs (femur and tibia) are known to be more robust, and the fibula is developed in quadrupedal bats. The femoral head is displaced from the main axis of the shaft, condition that is typically found in terrestrial mammals but absent in most bats. This gives the femur a pronounced “neck” and allows a frontal rotation with respect to the anterior tab of the acetabulum, which is limited in most bats because the femur head is aligned with the shaft, restricting the anterior movement of the femur and then the hind

limbs. This arrangement, coupled with changes in the musculature, allows the hind limbs to have greater efficiency during terrestrial locomotion (Vaughan 1959, 1970; Schutt and Simmons 2001; Louzada et al. 2019).

More recently, Louzada et al. (2019) have shown noticeable differences in femoral features, comparing a wide diversity of yangochiropteran bats. From their comparative analysis, they noted that quadrupedal bats have a sturdier femur than other bats and a set of anatomical characteristics that are exclusive or more developed: the shaft is straight; the trochanters are well-developed; the trochanteric fossa is deep; there is a tubercle in the greater trochanter, specially developed in *Mystacina* and molossids; and have associated this features to a greater musculature insertion and thus improved mobility of the hind limbs during crawling behavior. Another interesting result was observed in noctilionoids, which share some characters with quadrupedal bats, such as the sturdy femur, the straight shaft, and the developed trochanters; for them, however, the functional link is related to the use of the legs in trawling behavior (Celeita et al. 2018; Louzada et al. 2019).

Some modifications associated to quadrupedal habit are also described in the humeral morphology. Desmodontinae, for example, has a humerus with a spherical central capitulum, which allows considerable rotational movement (anteroposterior and lateral) in the elbow joint, while *Mystacina tuberculata* shares with the molossids a more restrictive bone joint between the humerus and radius, and presents a more pronounced radial inclination. Hand et al. (2009) showed that in *Mystacina*, the humerus has a deep supraepicondylar notch that is occupied by a tendon of the *extensor carpi radialis longus* muscle, which acts directly on the extension of the entire distal part of the wing and also aids in lifting the flight from the ground, which is important for quadrupedal species. Therefore, humerus morphology also reflects specializations in muscle morphology and muscle action and can be used to infer both flight mode and terrestrial capacity in extant bats (Schutt and Simmons 2001; Hand et al. 2009).

## Introduction

The name Chiroptera is derived from the Greek words *cheir* (=hand) and *pteron* (=wing), referring to the hand-like wings of bats, the primary adaptation for flight (Feldhamer et al. 2007). The wing is

formed from skin (patagium) stretched between the arm, wrist, and finger bones, which are light and slender. The forearm (radius and ulna), metacarpals, and fingers are elongated and, with the patagium, they form a structure that is “strong like an umbrella” (Neuweiler 2000). The thumb remains free and is the only digit that retains a claw in extant microbats. The wing membranes usually attach along the sides of the body and, besides their primary function in flight, they also aid bats in thermoregulation – the thin, vascularized membranes dissipate excess body heat generated during flight (Feldhamer et al. 2007).

Many skeletal features are associated with a need for strong or specialized attachments for the powerful flight musculature, which has influenced the architecture of the vertebral column, pectoral girdle, sternum, and first rib (Vaughan 1970). On the other hand, the hindlimbs are smaller than the forelimbs, presenting a 90-degree or more rotation around the longitudinal axis of the body, so the knees point backwards (Czaplewski et al. 2008). This is important to the upside-down roosting posture and aids in several flight maneuvers. A special locking tendon allows bats to cling surfaces without spending energy (Feldhamer et al. 2007).

Microbats encompasses representatives of the suborder Yangochiroptera plus Rhinolophoidea (Yinpterochiroptera) and are differentiated from megabats (Pteropodidae; Yinpterochiroptera) by the following features: tragus often well developed; nose or facial ornamentation often evident; no claw on second digit; cervical vertebrae modified; head is flexed dorsally from main axis of body when roosting; tail and tail membrane often evident; generally small body size; eyes generally small; mandible with well-developed, long, and narrow angular process; postorbital process usually absent; palate usually does not extend beyond the last upper molars; and presence of a neomorphic calcar (Gunnell and Simmons 2005; Feldhamer et al. 2007).

## External Morphology

There is a great range of size variation among microbats, from the small *Craseonycteris*

*thonglongyai* (2–3 g) to the large *Vampyrum spectrum* (130–235 g). Since they are nocturnal animals, a living coloration would be worthless and therefore most bats present only variations between black and brown, with some reddish or yellowish species (e.g., *Lamproncycteris brachyotis*, *Noctilio leporinus*). Even white fur may occur in some species (e.g., *Diclidurus* spp., *Ectophylla alba*) although this does not appear to increase its predation (Reis et al. 2007). The pattern of coloration is an important taxonomic tool that helps on the identification of some species, such as the tufts of white hair on the dorsal part of the forearm and the longitudinal stripes on the dorsal fur in *Rhynchonycteris naso* (Emballonuridae), the different facial strips patterns on some stenodermatines (e.g., *Platyrrhinus* spp.), the remarkable pattern of body fur coloration in *Nimbapha superba* (Vespertilionidae), and the stunning pattern of wing coloration in *Kerivoula picta* (Vespertilionidae) (Fenton and Simmons 2015; Reis et al. 2017). Besides taxonomy, the color pattern may function as a camouflage in roosting situations, potentially protecting bats from visually oriented predators. An example occurs in some reddish and yellowish lasiurine bats (*Lasiurus borealis* and *L. intermedius*) that roosts in the foliage of deciduous trees (Kunz and Fenton 2005).

Microbats usually have small eyes, large ears, well-developed tragus, nasal, and facial ornamentations, features primarily related to their echolocation system. The pronounced nose leaf of phyllostomids, for example, is important on the orientation of the ultrasonic pulses that come out from their nostrils. A projection from the lower margin of the ear, called tragus, is also important in echolocation (Feldhamer et al. 2007). On the other hand, the larger ears of gleaning bats, including some phyllostomids, are important to hear the sounds generated by insects or small vertebrates (Kunz and Fenton 2005; Reis et al. 2017). As the coloration patterns, the facial features are important to taxonomy: the flesh nose leaf present in Phyllostomidae, Nycteridae, Rhinolophidae, and Megadermatidae; the lips with folds and hairs around the muzzle that look like a mustache in *Pteronotus* spp.; the upper lip divided by two vertical grooves in Noctilionidae (Feldhamer et al. 2007; Gardner 2008).

Important structures to flight, the wing and uropatagium morphology also varies in bats. When viewed from above, wing shape varies from short and broad, to long and thin, being important to aerodynamics of flight. The uropatagium is the membrane between the hindlimbs that encloses the tail and may contribute to lift and to help on the stabilization of the body during turns and other maneuvers when bats are flying. A cartilaginous process, the calcar, helps to support the uropatagium. The size and shape of the tail membrane varies from extremely reduced (e.g., *Desmodontinae*) to well-developed, being sometimes even greater than the body length (e.g., *Natalidae*), and may completely enclose the tail (e.g., *Vespertilionidae*) or just a part of it (e.g., *Molossidae*) (Feldhamer et al. 2007; Reis et al. 2017).

## Skeleton

The bats skull is generally long and low with a rather long and narrow rostrum and somewhat inflated braincase. However, the configuration of the skull and jaws varies greatly in some species, reflecting primarily the strikingly diverse feeding habits, but also roosting habits, echolocation and flight styles, and other morphological correlates (Vaughan 1970; Czaplewski et al. 2008). The rostrum of nectar-feeding bats (e.g., *Glossophaginae* and *Lonchophyllinae*), for example, is narrow and elongated, while in frugivorous bats (e.g., *Stenodermatinae*), it is short and broad. Some bats have the skull strongly flattened which facilitate the access to small spaced roosts (e.g., *Tylonycteris robustula* lives inside of bamboo culm; molossids roosts in rock crevices) (Kunz and Fenton 2005), while bats that roost by hanging have skulls with well-rounded braincases (Vaughan 1970). Regarding to dentition, bats do not have the 44 mammalian pattern teeth, being 38 the greatest number of teeth that are usually present in most insectivorous groups (e.g., *Natalidae*, *Vespertilionidae*) and 20 the fewest number of teeth, present in the vampire bat *Desmodus rotundus* (Vaughan 1970). The incisors and canines retain their typical form in most bats,

but the former can be absent in some species (e.g., *Megadermatidae*). The first premolars are absent and additional lost occurs in many genera. The molars are W-shaped in most insectivorous species, being probably a primitive condition for bats (Czaplewski et al. 2008). The large neotropical family *Phyllostomidae*, however, presents a wide variety of molar morphology, according to its diet. The last molar is greatly reduced or lost in some members, usually associated with frugivorous and sanguivorous habits (Vaughan 1970). Like most mammals, newborn bats have a set of deciduous teeth that are precursors of the incisors, canines, and premolars. These teeth are slender, pointed, and sharply recurved and are used by the young bats to grip the mothers' nipples (Vaughan 1970; Neuweiler 2000; Fenton and Simmons 2015).

The axial skeleton of bats is similar to that of other mammals. In bats, the spine is usually made of 7 cervical vertebrae, 11 thoracic vertebrae, and up to 10 caudal vertebrae. The pectoral area is highly developed and modified, and some features seem to be related to flight in these mammals. The pectoral ring, which anchor the wings, is formed by the fusion of the manubrium, the first two ribs, and the last cervical and first two thoracic vertebrae. The thoracic vertebrae are tightly connected to one another to form a rigid column. The articulating scapula and proximal end of humerus are also highly modified for flight. The sternum presents a keel for the insertion of strong pectoral muscles, the clavicle is robust, and the scapula is parallel to the vertebral column, holding the muscles that controls the wing-beat cycle during flight. The body of bats is short and broad, due to both an anteroposterior compression of the cervical and thoracic vertebrae, and to a strong dorsal arching of the thoracolumbar section of the vertebral column. Therefore, their rib cages are large and often broader than deep. Also, the cervical vertebrae are twisted so the bat's head can stand raised during flight. The pelvis has undergone several adaptations that make it specially well suited for flight. In microbats, the ilium and the sacrum are fused together up to the level of the acetabulum (the socket into which the head of the femur fits), limiting the mobility at the iliosacral joint

(Vaughan 1970; Neuweiler 2000; Feldhamer et al. 2007; Reis et al. 2007).

The bones of the forelimbs form the wings of bats. The large and strong humerus is suspended from the scapula. The elongated lower arm is consisted of two bones: the radius, which is thick and sturdy, and the ulna, which is thin. There are six carpals, five metacarpals, and five sets of phalanges. The second to fifth metacarpals are greatly elongated and the thumb is free and is the only clawed digit of the manus. The hindlimbs primarily serve to support the wing membranes, so they usually are small, thin, and not very muscular, but there are few exceptions from species that have quadrupedal behavior (e.g., desmodontines, molossids, mystacinids). The femur is roughly the same length as the tibia, its head is large and slightly offset from the long axis of the shaft, which allows a great freedom of movements at the hip joint, important during hanging, fighting, and crawling behaviors. The tibia is the only bone in the lower leg, once the fibula is vestigial in most bats. The feet are usually short, the phalanges and claws are laterally compressed, and the calcar is usually well developed and projects into the adjacent border of the uropatagium, which is important to keep the posterior part of the tail membrane extended (Vaughan 1970; Neuweiler 2000).

It is worth noting that studies on the postcranial anatomy may increase and improve the descriptions and identifications of bats that usually are made based on cranial characters. Recent researches on this area have been showing a great potential on taxonomic, phylogenetic, evolutionary, and morphofunctional studies (Gardner 2008; Gaudioso et al. 2017). From the paleontological view, such studies are also noteworthy, allowing the identification of extinct and extant specimens from fossil records, which many times are composed by fragmented bones (e.g., Czaplewski et al. 2008).

## Families Characterization

Despite the general description given above for both external and skeleton morphology of bats, each family presents a set of features that allow

their differentiation from other families. Below, we describe a brief characterization of each family of microbats, based on Hill (1982), Hooper and Van Den Bussche (2003), Garbutt (2007), Feldhamer et al. (2007), Lack et al. (2010), Happold and Happold (2013), Fenton and Simmons (2015), Stuart (2015), Armstrong et al. (2016), and Reis et al. (2017).

**Cistugidae:** The wing-gland, pimple-winged, or hairy bats formerly were grouped in the large genus *Myotis* (Vespertilionidae). The unique feature that distinguishes them from other bats is the presence of one or two pronounced pimple-like glands on the plagiopatagium of each wing, just near the forearm, that are evident in living animals, but may not be observed in dried museum specimens. There are only two species representing this family: *Cistugo lesueuri* and *Cistugo seabrae*. They are small bats and have a great color variation of their dorsal dense pelage. The tragus is long and narrow but not sharply pointed. Their tail is long and enclosed in the uropatagium.

**Craseonycteridae:** This monotypic family comprises the smallest species of bat, the hog-nosed bat *Craseonycteris thonglongyai*. They have large ears and tragus, and a distinctive plate on the nose. The tail and the calcar are absent, the uropatagium is large, and the wings are broad.

**Emballonuridae:** The sac-winged bats have this name in association to their most remarkable feature – wing sacs on the ventral surface of the wings, near the elbow. These sacs, that are more developed in males, exude a red, odiferous substance that is probably important in pheromone production and attraction of females. The ears are short and the long uropatagium is drilled in the upper face by the tail, which has its end free.

**Furipteridae:** The species of this family are known as smoky or thumbless bats. They have large and well-separated ears with a small triangular tragus, and dense fur. Their thumb appears to be absent, once it is very small and mostly enclosed in the wing membrane. The tail is long and enclosed in the long uropatagium.

**Hipposideridae:** They have an elaborate nose leaf (leaf-nosed bats), which consists of fleshy protrusions above the nostrils. These ornamented

nose leaf present a great diversity in size and shape, varying among species. The size of the ears varies and the tail can be absent.

**Megadermatidae:** Known as false vampire bats by the false belief that they feed on blood, megadermatids have large ears that are united on the forehead, a divided tragus, and a large, erect nose leaf. All species lack upper incisors. The uropatagium is extensive, but the tail is short or absent.

**Miniopteridae:** They are known as long-winged or bent-winged bats and were first considered as vesper bats. However, some apomorphies distinguish them from all other vespertilionids. They have a prominent rostrum, the second phalanx of the third finger is about three times as long as the first, the baculum is absent, and there is a supplementary vestigial tooth between the upper canine and the first premolar. They have a long tail that is enclosed in the long uropatagium.

**Molossidae:** The free-tailed bats have a long and robust tail that extends well beyond the outer edge of the uropatagium. They have large ears that point forward and a tragus that is nearly rounded. The wings are long and narrow, the thumbs are short and thick, with a swollen base.

**Mormoopidae:** The species of this family are known as mustached, ghost-faced, or naked-backed bats. They have reddish-brown or dark brown coloration, the ears are short, and the tail projects dorsally from near middle of the long interfemoral membrane. The lips are enlarged and surrounded by numerous stiff hairs ("mustached"). Some species have the wings meeting middorsally, obscuring the fur ("naked-backed") and some have conspicuous, leaflike appendages on the chin ("ghost-faced").

**Mystacinidae:** The New Zealand short-tailed bats have a long snout, and their slit-like nostrils are located in a pad covered with bristles. The ears are moderately developed with a long and pointed tragus. They have very sharp claws on the hind feet and thumb, and a thick membrane along the side of the body where they can hide their wings when walking on the ground. The short tail projects from midpoint of dorsal surface of a medium-sized uropatagium.

**Myzopodidae:** The sucker-footed bats have suction disks on their wrists and ankles, not related with those in thyropterids. They have a unique mushroom-shaped process at the base of their large ears. Their toes have only two phalanges, and the thumb is small with a vestigial claw. The tail is long and extends beyond the well-developed uropatagium.

**Natalidae:** The funnel-eared bats are small bats with a long dorsal pelage that varies from yellow to reddish-brown. The tragus is short, and the large ears are funnel-like, giving these bats their common name. The forehead region is domed, and there are no ornaments on the face, although the males have a mass of glandular sensory cells (called natalid organ) on their muzzle. They have a well-developed uropatagium, which encloses the long tail.

**Noctilionidae:** Known as bulldog bats, noctilionids have a remarkable yellow to brown pelage coloration and a cleft upper lip. The hindlimbs are well developed, as the feet and claws, and the tail extends halfway through the long uropatagium. The ears are separated, narrow, and pointed.

**Nycteridae:** The slit-faced bats have this name due to the unusual longitudinal groove throughout the facial region, given by the deep concavity between the eye orbits. They have large ears and small tragus. The uropatagium is long and encloses the tail, which forms a unique T-shape on the tip.

**Phyllostomidae:** The leaf-nosed bats have a nasal ornament usually in the form of leaf or lance, that varies from highly developed (e.g., *Chrotopterus* and *Lonchorhina*) to extremely reduced and modified (e.g., *Desmodus*, *Diaemus*, and *Diphylla*, which have a horseshoe-shaped nose leaf). Their ears vary greatly in size and shape, and the tragus is always present. The tail may or may not be present, but when present is completely enclosed in the uropatagium. Some species have a well-developed uropatagium (e.g., *Macrophyllum macrophyllum*), but it can be almost absent in another species (e.g., *Desmodus rotundus* and *Sturnira lilium*).

**Rhinolophidae:** The horseshoe bats are named by their distinctive facial ornamentation,

which varies from simple to very ornate, and includes a nose leaf above the nostrils, and horseshoe-shaped flaps below and on the sides of the nostrils. Between the horseshoe and the nose leaf there is a median projection called sella, which differs them from hipposiderids. The ears are large and pointed, lacking the tragus. The wings are broad and rounded, the uropatagium is well-developed, with the tail extending up to its end.

**Rhinonycteridae:** The trident bats and the diamond-faced bats are named by one of their most conspicuous external features, a complex nose leaf, which have three dorsally oriented fleshy processes in the posterior rhinarium in most genera (trident bats), and a diamond-like nose leaf, with the anterior leaf more or less pentagonal in outline in *Rhinonycteris* (diamond-faced bats). They have a flattened muzzle, and the ears can be short or large, usually pointed. The tail is long and its tip may exceed the margin of the long uropatagium in some species.

**Rhinopomatidae:** Also known as mouse-tailed bats, they have a long tail, nearly equal to their body length and even longer than their forearm. The uropatagium is short and most of the tail is free. The ears are large and connected across the forehead by a flap of skin. They have dark dorsal fur and paler ventral fur, being some areas of the face, rump, and abdomen, naked.

**Thyropteridae:** The disk-winged bats have this name due to their round and concave suction disks at the base of the thumbs and on the soles of the feet. They are small bats with a long and slender snout and have small warts above their nostrils. The ears are moderately large and funnel-shaped, and the tragus is present. Their feet are tiny, with fused toes. The tail is long and extends beyond the well-developed uropatagium.

**Vespertilionidae:** The vesper bats present a great variation of size, pelage coloration, and morphology features. They have small eyes and ornaments on the nose are usually absent, although their face may be adorned with swollen glands and other structures. The ears vary in size and shape, some species with small rounded ears (e.g., *Lasiurus*

*cinereus*) and other ones with elongated ears (e.g., *Histiotus*). A well-developed tragus is usually present. Their tail is well developed and extends to the edge or beyond of a V-shaped uropatagium.

## Functional Morphology

Morphological characteristics of bats may represent functional adaptations related to the habitat use, foraging strategies, styles of terrestrial locomotion, and roosting behavior. The wing morphology, for example, is related to the flight pattern and habitat use of bats. A long and narrow wing, with small surface area, adapts a species for sustained, relatively fast flight, as is seen in noctilionids and many molossids, that forage high above the ground, predominately in open unobstructed environments, as the region above the forest canopy or over water. A short and wide wing, with large surface area, is present in bats with slower, more maneuverable flight, as seen in carnivorous bats (e.g., *Chrotopterus auritus*, *Vampyrus spectrum*, *Nycteris grandis*, *Cardioderma cor*), that forages more often in habitats with dense, obstructing understory vegetation. Intermediate patterns of wing morphology, present in some gleaning frugivores (Stenodermatinae and Carollinae), indicate flexibility in the use of space and resources (Feldhamer et al. 2007; Marinello and Bernard 2014).

Some bats have specializations related to roosting behavior, having morphological features that allow them to occupy different habitats. *Neoplatymops mattogrossensis*, for example, have the forearm with small wart-like granulations on dorsal side, which is related to their crevice-dwelling habits. Specimens of Thyropteridae and Myzopodidae have rounded, concave, suction disks at the base of the thumbs and on the soles of the feet that make possible for them to cling to stems, furled leaves, and other smooth surfaces; these disks, however, differ anatomically, and evolved independently in each family, being an example of convergent evolution (Kunz and Fenton 2005; Feldhamer et al. 2007).

Regarding to foraging strategies, *Noctilio leporinus* and *Myotis vivesi* have very long and large hindlimbs, rake-like feet with well-developed claws to scoop up aquatic and terrestrial prey. Among sanguivorous bats, *Diphylla ecaudata* is the only one that retains a functional calcar. The behavior of this vampire indicates that it is an arboreal hunter, and its calcar can be used as an opposable sixth digit to facilitate branch-grasping during arboreal locomotion, while they are stalking its prey (Schutt 1998).

Some features are related to the quadrupedal habit of some bats. Desmodontines and molossids have metacarpal pads to support the hindlimb during the terrestrial locomotion (Schutt and Simmons 2006). Mystacinids have very sharp claws on the hind feet and thumb, each with a small, basal talon. They also have a thick membrane along the side of the body, where the wings can be folded up, during the quadrupedal behavior (Feldhamer et al. 2007).

## Microchiroptera Sensory Systems

Amaro Tuninetti<sup>1</sup> and Andrea Megela Simmons<sup>2</sup>

<sup>1</sup>Brown University, Providence, RI, USA

<sup>2</sup>Department of Cognitive, Linguistic, and Psychological Sciences, Brown University, Providence, RI, USA

### Definition

Auditory, visual, and olfactory capacities of echolocating bats.

### Introduction

Bats are one of the most evolutionarily successful mammalian groups, occupying a wide variety of ecological niches and adapted to a range of lifestyles. As members of the order Chiroptera, they have traditionally been categorized as either Microchiroptera (microbats) or Megachiroptera (megabats), although this categorization has been updated and revised (Teeling et al. 2005). This entry concentrates on the microbats, of which there are nearly 1,000 recognized species. These bats use laryngeal echolocation to perceive their surroundings by emitting ultrasonic sounds from their mouth or nostrils and then listening to the returning echoes reflected back from nearby objects. Hearing is the primary sense that echolocating bats use for short-distance orientation, obstacle avoidance, and foraging. Bats are not blind, but their vision is adapted to seeing at low light levels and for navigating on large spatial scales. Nectar- and fruit-eating bats use their vision and their sense of smell to locate flowers and fruits; for these bats, these senses supersede echolocation in foraging but not in obstacle avoidance. Bats also use their sense of smell to recognize conspecifics in crowded roosts. This review will summarize current understanding of auditory, visual, and olfactory senses in guiding the behavior of laryngeal echolocating bats.

### Audition

Echolocation is a unique and specialized perceptual system that has evolved as an adaptation to support nocturnal behaviors. It allows bats to navigate spaces that other visually adapted nocturnal mammals cannot take advantage of, such as deep cave systems where no ambient light reaches, and to perceive the distance, size, shape, horizontal location, and vertical location of objects. For the purposes of echolocation, the auditory and vocalization systems of bats have evolved to use ultrasonic frequencies (i.e., above 20 kHz, the limit of the human range of hearing). While these high-frequency sounds do not propagate through the environment as far as do sounds of lower frequency, high frequencies with their short wavelengths are much better suited to provide information about the shape, size, and texture of small objects such as insects. Though there are some prominent similarities in the auditory systems of all echolocating bats, there is nonetheless considerable variability in the precise auditory capabilities across species. Each species has its own calls and emission patterns as an acoustic adaptation to its lifestyle and the unique challenges it faces in the wild (Griffin 1958; Neuweiler 2000). This section aims to give an overview of the auditory systems of this group as a whole while highlighting the unique characteristics that have arisen in certain species as a function of their echolocation.

### Anatomy

If a bat's mouth or nostrils is its biosonar "transmitter," then its two external ears, or pinnae, are its signal receivers. Pinnae are the only externally evident component of the auditory system, and the bat's pinnae, as in all mammals, act to amplify sound and direct it efficiently toward the eardrum for optimal sensitivity. Though all echolocating bats have relatively large pinnae – a clear indicator that they rely heavily on audition – differences in the complicated pinnae shape and size across species reflect variability in bat ecology and what sounds they produce and hear.

One of the central purposes of the pinnae is to amplify the external sounds entering the ear

canal before they hit the eardrum. The amount of amplification, or gain, depends partially on the size of the pinnae. Larger pinnae capture more acoustic energy from the air and more effectively amplify lower sound frequencies, because the longer wavelengths of low frequencies can interact more with the larger pinnae surface areas. This is illustrated by the fact that gleaners (such as the greater false vampire bat, *Megaderma lyra*, and the fringe-lipped bat, *Trachops cirrhosus*) have very large pinnae. These bats detect their prey (insects, frogs, small mammals) not by active echolocation but by remaining perched and passively listening for the low frequency sounds that these prey make while moving on the ground or vocalizing. The massive pinnae of these gleaners disproportionately amplify these prey-generated low frequencies (Obrist et al. 1993). In contrast, nectar-eating and fruit-eating bats tend to have relatively small and simple pinnae.

Pinnae also act to increase the directionality of sounds reaching the ear, selectively amplifying or attenuating (decreasing) the amplitudes of sounds entering the ear from specific angles. This gives the bat additional cues for sound direction. The amount of directionality exerted upon a particular sound varies with the size and geometry of the pinnae as well as with the sound frequency; in general, pinnae show increasing directionality at frequencies greater than 5 kHz (Obrist et al. 1993). Directionality also changes based on the type of echolocation calls a particular species emits. Frequency-modulating (FM) bats emit short duration broadband echolocation calls sweeping downward from 100 kHz to 20 kHz, and their pinnae generally exert moderate directionality across a broad range of frequencies. Constant-frequency (CF) bats emit much longer duration echolocation calls that consist of only a narrow band of ultrasonic frequencies; the pinnae of these species display very sharp directionality at the specific frequencies of these calls (Obrist et al. 1993). Echolocating bats have an additional structure in their pinnae called the tragus, a small leaflike structure that stands upright in front of the pinna. The tragus selectively changes the amplitude of incoming sounds based on the vertical angle with which they enter the

pinnae. This effect acts to provide information to the bat on the vertical position of sound (Lawrence and Simmons 1982).

The remainder of the auditory system of bats follows the typical mammalian pattern: sounds are transmitted to the tympanic membrane, through the middle ear, and then to the cochlea, where hair cells transduce incoming vibrations into neural signals that are then transmitted to the brain. Bats have relatively huge cochleae compared to similarly sized mammals. The width of the cochleae in greater horseshoe bats (*Rhinolophus ferrumequinum*) ranges from 2.6 to 4.3 mm, while the cochleae of similarly sized mice average 1.15 mm (Habersetzer and Storch 1992). There is another adaptation in the cochlea which greatly affects the bat's sense of hearing. The cochleae of the FM bats represent equally well all frequencies of sound to which the bat is sensitive. In contrast, many CF bats have an "acoustic fovea" – their cochlea disproportionately overrepresents the small range of frequencies in their CF echolocation call, making the bat's hearing much more sensitive to those frequencies than to others in their audible range. For example, in the greater horseshoe bat, a full 25% of the cochlea's hair cells are sensitive to frequencies of 80–86 kHz, which is just 6% of the bat's frequency hearing range but represents the frequencies in its CF echolocation call (Bruns and Schmieszek 1980).

### Hearing Sensitivity

All echolocating bats hear ultrasonic frequencies, but how sensitive their hearing is within this frequency range varies across species. In addition, bats use hearing for purposes other than active echolocation. The gleaners must be able to hear the low frequencies emitted by their prey in order to hunt (Neuweiler 2000). Furthermore, bats have extensive repertoires of social communication calls used for individual identification, mother-pup recognition, and communication of emotional state. Social calls typically contain frequencies lower than those in echolocation calls and in some cases extend below the ultrasonic range (Bohn et al. 2006). To perceive echolocation calls and echoes, sounds made by prey

**Microchiroptera Sensory Systems, Fig. 1** Behavioral audiograms showing the frequency sensitivity of hearing of four species of bats, as indicated by different colors. The big brown bat (*E. fuscus*) and the pale spear-nosed bat (*P. discolor*) are FM bats; the greater horseshoe bat (*R. ferrumequinum*) is a CF bat; and the greater false vampire (*M. lyra*) is a gleaning bat. Each colored plot indicates for each species the threshold for detection of pure tones at the indicated frequencies. Valleys indicate the frequency ranges of heightened auditory sensitivity (lowest thresholds) for each species. The colored bars next to the species names indicate the frequency range of

that species' emitted echolocation calls. The two FM bats emit echolocation calls with broader frequency ranges than the CF bat. The greater false vampire bat has better hearing sensitivity than the FM and CF bats in the low-frequency region below 10 kHz. Colored arrows below the x-axis indicate the peak frequencies of contact calls or isolation calls emitted by pups of each species. These frequencies are below those in echolocation calls but remain within the range of good hearing sensitivity. (Adapted from Esser and Daucher (1996), Esser and Schmidt (1989), Koay et al. (1997), Long and Schnitzler (1975), and Neuweiler (1984, 2000))

and social calls, the bat's auditory system must function over a wide range of frequencies.

Figure 1 plots behavioral audiograms for one primarily CF bat (the greater horseshoe bat), two FM bats [the big brown bat (*Eptesicus fuscus*) and the pale spear-nosed bat (*Phyllostomus discolor*)], and one gleaning bat (the greater false vampire bat). Each species hears with greatest sensitivity (lowest thresholds) the frequencies in its echolocation calls. The greater horseshoe bat shows an extremely sharp peak in hearing sensitivity at the 86 kHz component in its CF echolocation call, and another region of broader sensitivity around the frequencies contained in the isolation calls of its pups (Long and Schnitzler 1975). The big brown bat's echolocation calls extend from 20 to 90 kHz, and the bat shows greatest sensitivity within this range. The increased thresholds within the range of 45–50 kHz are due to filtering by the pinnae (Koay et al. 1997). The pale spear-nosed bat has

less sensitive hearing than the other bats, but with two regions of good sensitivity. The high-frequency peak of sensitivity around 60–90 kHz covers the range of its echolocation calls, and the low-frequency peak between 20 and 40 kHz covers the range of its social communication sounds (Esser and Daucher 1996). Pale spear-nosed bat pups emit isolation calls with frequencies around 16 kHz (Esser and Schmidt 1989). The greater false vampire bat emits brief broadband (20–120 kHz) echolocation calls and is very sensitive within this frequency range. Contact calls of this species have energy concentrated at 20 kHz. The comparatively good hearing sensitivity below 20 kHz allows these gleaning bats to detect sounds made by moving or vocalizing prey (Neuweiler 2000).

### Detection and Identification of Echoes

The identification of objects based on their reflected echoes is crucial for the survival of

echolocating bats. Not only do bats need to identify general properties of spaces and surfaces for navigation and roosting purposes, but their environments also require discriminating between different objects for successful foraging – whether they eat insects, vertebrates, fruits, or nectar. Bats are able to hear weak echoes from small insect prey or from small obstacles in the environment, even though these echoes are much fainter than those returning from large obstacles such as trees or buildings. Their hearing sensitivity is so high that they can detect thin wires as much as 50–60 times smaller than the wavelength of their echolocation call. For example, the greater horseshoe bat can detect wires with a diameter of just 0.08 mm, while the Mediterranean horseshoe bat (*Rhinolophus euryale*) and Mehely's horseshoe bat (*Rhinolophus mehelyi*) can detect wires of 0.05 mm diameter (Schnitzler and Henson 1980).

Bats can readily discriminate between objects of different sizes, textures, and shapes. North American insect-eating bats will pursue small pebbles thrown into the air but desist after a few attempts (while still hunting insects), demonstrating they can clearly distinguish between edible and inedible objects of similar size (Griffin 1958). To discriminate objects of different size, a bat must perceive differences in the amplitudes of returning echoes. When ensonified, two objects of equal shape and texture will reflect echoes with identical frequency compositions, but the larger object will simply reflect more acoustic energy than the smaller one. Greater bulldog bats can discriminate between cylinders of different sizes if their returning echoes differ by just 1 dB, and big brown bats can discriminate triangular targets of different sizes when echo intensity differences are 1.5–3 dB. Beyond an object's size, bats can discriminate objects of different shapes, textures, and materials based on differences in their reflected echoes. Spectral bats (*Vampyrum spectrum*) are able to discriminate between spheres and elongated spheres that reflect echoes of equal amplitude; serotine bats (*Eptesicus serotinus*) can discriminate between targets covered in glass and targets covered in velvet; and lesser mouse-eared bats (*Myotis blythii*) and greater horseshoe bats can discriminate between

aluminum, plexiglass, plywood, and resinous plates. Big brown bats can discriminate between metal plates with small holes drilled partway into them, even when the depth of the holes differ by as little as 0.6 mm. Bats use acoustic cues in returning echoes to make these behavioral discriminations (reviewed in Moss and Schnitzler 1995).

### Localization of Echoes

Ranging refers to a bat's ability to perceive the distance to an object. With echolocation, this is a matter of precisely measuring the amount of time that passes between the emission of an echolocation call and the reception of any echoes. Big brown bats and greater spear-nosed bats (*Phyllostomus hastatus*) can accurately distinguish between two identical surfaces whose distances are only 12 mm apart, even when these surfaces are presented at different overall distances from the bat and thus reflect echoes at different intensities (reviewed in Moss and Schnitzler 1995).

In addition to target distance, CF bats can detect a target's relative velocity from a single reflected echo – that is, whether the target is moving toward or away from them. They do this by detecting the Doppler shift in the returning echo and comparing it to their original echolocation call. When a CF bat approaches a target, the narrow band of frequencies in its echolocation call is compressed by the bat's forward motion, causing an upward Doppler shift in the frequency of the echoes that are then detected by the bat. Similarly, if a target is flying quickly away from the bat, a reflected echo's frequencies will be Doppler shifted downward. Greater horseshoe bats can detect Doppler shifts as small as 10 Hz, allowing them to accurately determine the velocity of a target relative to themselves (Schnitzler and Henson 1980). Moreover, these bats can adjust their CF broadcasts to emphasize objects moving at a particular velocity.

Determining a sound's position in three-dimensional space requires measurement of both its azimuth (horizontal position) and elevation (vertical position). Bats can determine the azimuth of a returning echo by comparing cues

from the two ears. Big brown bats can detect differences in the time of arrival of sounds at the two ears with an accuracy of 1  $\mu$ s, corresponding to an azimuth difference of 1.6° (Masters et al. 1985). Differences in intensity of echoes at the two ears are caused by the sound shadow produced as sound travels around the head. The small heads of the Indian roundleaf bat (*Hipposideros lankadiva*) cast enough of a shadow to significantly reduce the intensity for echoes of its high frequency sounds as they travel from the closer ear to the farther ear by as much as 40 dB SPL (Obrist et al. 1993). The elevation of a sound is determined with the help of acoustic cues caused by the tragus. Big brown bats are able to discriminate thin metal rods separated vertically by 3°, but this accuracy decreases to 12–14° separation when the tragus is physically moved out of the way (Lawrence and Simmons 1982).

### Vestibular Sensing

Mammals use their vestibular systems to monitor balance and the body's position in space in relation to gravity. Precise vestibular input through the semicircular canals and the otolith organs in the inner ear is extremely important for animals who use powered flight to navigate and maneuver in three dimensions. But, unlike birds, echolocating bats do not have larger semicircular canals than expected on the basis of their body size (Davies et al. 2013). This may be due to space constraints in the bats' inner ear caused by their disproportionately large cochleae.

Big brown bats can maneuver with great agility through static or rotating arrays of obstacles. If they are given deuterium oxide (heavy water) rather than tap water to drink, they fly more slowly, more erratically, and they collide with obstacles more frequently, even though they continue to echolocate (Horowitz et al. 2004). Heavy water disrupts the mechanical responses of the otolith organs, the inner ear organs that provide information about linear acceleration through space, without disrupting hearing. Bats may rely on vestibular cues in combination with

echolocation to keep their bodies correctly oriented when performing complex flight maneuvers.

### Vision

Echolocating bats are not blind. Many species have eyes adapted for vision in dim light, as shown by their small eyes, large corneas, and retinas densely packed with rods (Suthers and Wallis 1970). Insect-eating species typically begin foraging at dusk, when low levels of ambient light are still present. Little brown bats (*Myotis lucifugus*) will echolocate across a range of ambient light levels, but they will collide more often with obstacles having little visual contrast as light levels increase (Orbach and Fenton 2010). This suggests that in some environmental conditions, some species may pay attention to visual cues, even when this disrupts orientation by echolocation. The California leaf-nosed bat (*Macrotus californicus*) hunts desert insects by hovering above the ground. It can locate its prey with comparable success using vision (at moderate levels of ambient illumination) and using echolocation (in total darkness). When light is available, this bat echolocates less than it does in darkness. The visual acuity of California leaf-nosed bats is 3' of arc, while that of big brown bats, which hunt insects in the air, is 60' of arc (Bell and Fenton 1986). But other species continue to rely on echolocation even in moderate light levels. Kuhl's pipistrelle (*Pipistrellus kuhlii*), a bat that hunts insects near vegetation, and the greater mouse-tailed bat (*Rhinopoma microphyllum*), a bat that hunts insects in open space, use echolocation in preference to vision when hunting small prey at different levels of ambient illumination (Boonman et al. 2013). Big brown bats can maneuver through complex arrays of small obstacles using echolocation alone. Their performance does not improve when visual cues are provided, unless their vestibular senses have also been disrupted (Horowitz et al. 2004).

Bats that forage on fruits and nectar rather than on insect prey rely on visual cues rather than on echolocation for detecting and localizing their

food sources. The fruit-eating bats Seba's short-tailed bat (*Carollia perspicillata*) and Pallas' long-tongued bat (*Glossophaga soricina*) have in their retinæ cone receptors that are sensitive in the ultraviolet range (Müller et al. 2009). The ability to detect ultraviolet light may help these bats find flowers that reflect in the ultraviolet range and to orient at twilight, when ultraviolet cues are visible in the sky (Winter et al. 2003).

Common vampire bats (*Desmodus rotundus*) feed by drinking blood from large warm-blooded prey such as cattle and pigs. These bats use echolocation for orientation and initial approach to the prey. They then land on the animal and search for a suitable place to feed by detecting maximal regions of heat (infrared radiation) on the skin. Vampire bats can detect temperature differences between warm and cold objects at distances of up to 16 cm using a group of three pits located on their face around their nose leafs (Kürten and Schmidt 1982). These pits function as simple "pinhole" sensors for detecting the long wavelengths of radiated body heat. The array of receptors inside each pit organ supplies to the bat a degree of directional information about nearby warm surfaces.

## Olfaction

Fruit- and nectar-eating bats also use odors rather than echolocation to find food. These bats tend to have larger olfactory bulbs than do bats that forage via echolocation, although nasal cavities and olfactory areas of the brain are highly variable in size and structure across different bat species (reviewed in Bloss 1999). Even so, fruit- and nectar-feeding bats have acute senses of smell, and olfactory cues alone can guide choice of flower or fruit in these species. Seba's short-tailed fruit bat can distinguish ripe from unripe fruit and natural from synthetic food odors. Pallas' long-tongued bat prefers sulfur-containing floral scents that are the natural components of the flowers that this species pollinates (Bloss 1999; von Helversen et al. 2000).

Insectivorous species forage using echolocation rather than by detecting odors; however,

these bats use olfactory cues to recognize conspecific bats in the large, often crowded roosts (maternity colonies) in which they live and give birth. The sources of these odors could be from specialized glands, urine, feces, or metabolic byproducts of diet (Bloss et al. 2002). Female big brown bats can distinguish between the smells of females from their own colony and those of females from other colonies. In two-choice tests, they spent more time in the arm of a Y-maze containing the odor of a familiar than that of an unfamiliar female (Bloss et al. 2002). Bats living in the same roost have similar bacterial compositions in their body secretions, and these may serve as a sort of odor signature. Greater sac-winged bats (*Saccopteryx bilineata*) have scent pouches on their wings that contain odorants that they secrete during courtship displays. These odorants differ in chemical composition from those found in the scent pouches in the closely related species, the lesser sac-winged bat (*Saccopteryx leptura*) (Caspers et al. 2009), suggesting that each species has its own olfactory signature. Female sac-winged bats prefer the scents of males of their own species over the scents of the males of the lesser sac-winged bat.

Olfactory cues are also important in mediating mother-pup recognition in maternity colonies. In two-choice tests, female Mexican free-tailed bats (*Tadarida brasiliensis mexicana*) can discriminate between the odors of their own nursing pups and those of unrelated pups. These females mark their pups with odors from their own muzzles as a way to recognize them in these large colonies (Gustin and McCracken 1987).

## Conclusion

The sensory systems of echolocating bats have developed in specialized ways to allow these species to occupy a unique ecological niche as nocturnal foragers. Their auditory systems are tuned to hear faint ultrasonic frequencies (>20 kHz) and allow them to distinguish fine detail in their surroundings by sound rather than by sight or smell. Bats that are aerial insectivores are more reliant on echolocation than are those species

that forage on fruits and flowers, but even those species echolocate to orient and avoid obstacles. Even within the nocturnal niche, sensory capabilities of bats differ depending on their particular ecology and foraging habits. The vision of echolocating bats is in general not as well-developed or sensitive as their hearing, but is nevertheless well-adapted to low-light situations and quite suitable for long-range navigation. Still, some bats have better visual capabilities than others. The use of vision is of particular importance considering that the effective range of echolocation is no more than several tens of meters. For bats roosting in large colonies (up to tens of millions of conspecifics), olfaction is required for distinguishing between conspecifics and close relatives. The sense of olfaction is arguably even more important for fruit- and nectar-eating bats, who often rely on their sense of smell to find food among vegetation. Finally, though little is known concerning the vestibular sensitivities of bats, these are undoubtedly highly developed and sensitive. Like other flying animals, bats rely on an acute sense of balance, acceleration, and spatial positioning in order to remain airborne while executing complex and sudden maneuvers. In short, exploring the sensory systems of echolocating bats provides a unique look into the lives of these fascinating animals, the ecological pressures present in their environments, and the strategies they have developed to overcome these difficulties.

## Microchiropteran Communication

Angeles Salles and Kirsten M. Bohn  
Johns Hopkins University, Baltimore, MD, USA

### Definition

Communication occurs when a signal produced by an animal provides information to conspecifics (animals of the same species).

## Introduction

Nearly all microchiropterans are highly social; whether living in small tight-knit clusters or large aggregations or even complex societies (see Kerth 2008), they continuously interact with conspecifics in their roost sites. This entry presents an overview of *social communication signal transmission* in bats. Social communication signals can be *olfactory*, *visual*, *tactile*, or *acoustic*. Bats use all four modalities for social communication but rely most heavily on acoustic and olfactory communication signals.

## Acoustic Communication

One defining feature of microchiropterans that is rare among animals is reliance on acoustic *auto-communication*, meaning communicating with oneself, by actively producing signals in the form of *echolocation* calls to navigate (see Box 1). Not only can these calls be used by other eavesdropping bats, to determine the presence and location of the caller (including potential food); reports on various species indicate that echolocation calls can also provide social information such as individual identity, group membership, or sex (reviewed in Bohn and Gillam 2018). Specializations for the sophisticated auditory-vocal system required for echolocation have also had a large impact on the evolution of acoustic social communication, which is by far the most common modality of communication in bats. Considering the degree of sociality in bats, it is not surprising that every species studied uses social communication calls in addition to echolocation. These range from modified echolocation-like calls to simple “squawks” during confrontations to complex hierarchical songs used in courtship.

In addition to echolocation signals that can provide social information, specialized vocalizations for social communication are produced by most if not all bat species with acoustic properties that are distinct from echolocation. Social calls are extremely common if not ubiquitous in roost sites. Some species also produce distinctive social calls in flight. The acoustic range of vocal

communication signals is extremely diverse, varying greatly within and among individuals and species. Commonly but not always, social communication calls are lower in frequency and longer in duration than echolocation. Frequencies range from the audible range (approximately 5 kHz) to ultrasonic (up to 80 kHz). The form of syllables (individual sound elements) can be “noisy” such as “squawks” or “screams,” to clicks, to tonal signals that sound like whistles. In many species, some calls are multisyllabic, that is, they consist of multiple elements; these signals vary from a few to hundreds of syllables. For example, one of the most common multisyllabic signals across microchiropteran species are “buzzes” – rapid successions of short *frequency-modulated sweeps*. Given the diversity of microchiropterans and long evolutionary history of the order Chiroptera, it is not surprising that repertoire size and complexity vary immensely. Relatively complete repertoires have only been documented on a small percentage of bat species, and given the difficulty in observing bats in their natural habitats (such as dark caves or in flight), the functions of many vocalizations are poorly understood. Generally, however, communicative vocalizations can be grouped into the following functional categories: *conflict resolution, mating, and social integration*.

#### Box 1

Microchiropteran bats use auto-communication in the form of echolocation signals. Other bats can eavesdrop on these signals. In social communication systems, the production of signals evolves to evoke a favorable behavioral response from the receiver.

### Conflict Resolution

Conflict resolution vocalizations are produced in adverse situations either from an external threat (distress calls) or during conflicts among individuals (agonistic calls). All bats, like most mammals, produce distress calls. In bats, these calls are predominantly low-frequency, noisy “scream-

like” calls that are often produced in bouts. These bouts may repeat and are thought to carry redundant information. Agonistic calls are also common in bats and take the form of low-frequency, noisy “squawks,” buzz-like calls (i.e., a rapid set of downward frequency-modulated sweeps), trills, and warbles. In roost sites, these commonly occur when bats quarrel over roost space. Mildly aggressive encounters between bats of either sex may start with down sweep vocalizations switching to more noisy screech-like calls as aggression escalates. In some species, during mating seasons, males use extensive agonistic calls and/or songs while maintaining roost site territories where they permit females to reside but aggressively defend against males. In some species, these vocalizations are accompanied by specific postural displays such as wing flapping or boxing.

Agonistic calls are also produced in flight in many species. For example, “honks” have been well noted across taxa to avoid midair collisions. “Buzzes” are frequently heard at foraging sites for many species. More complex agonistic calls are common in those species that defend foraging territories (e.g., *Pipistrellus* species reviewed in Bohn and Gillam 2018). Finally in competitive foraging contexts, some species produce food claiming calls (e.g., big brown bats, *Eptesicus fuscus*, Wright et al. 2014) or calls that directly interfere with the echolocation of competitors (Brazilian free-tailed bats, *Tadarida brasiliensis*, Corcoran and Conner 2014).

### Mating

During the mating season, males of a handful of bat species produce elaborate songs to attract females and repel conspecifics. Singing behavior is not ubiquitous in bats but has evolved in at least five families (reviewed in Smotherman et al. 2016), making it far more common than in other mammalian groups. Songs can be composed of hundreds of syllables and have multiple types of phrases. In some cases, syllables used for other communicative purposes such as aggressive buzzes or isolation calls (see below) may be combined to build songs used during mating (Bohn et al. 2008). For example, in the Brazilian

free-tailed bat, songs are comprised of syllables that are combined to form phrases, phrase order typically follows precise syntactical rules, and specific phrase combinations are preferred over others depending on social context (Bohn et al. 2013). Nevertheless, songs are flexible, varying in syllable number, phrase order, and phrase repetitions. In another species, *Saccopteryx bilineata*, songs are composed of over 20 types of syllables, can contain multiple types of information such as geographic and individual signatures, and are at least partially vocally learned (reviewed in Knoernschild 2014; Smotherman 2016). The fundamental frequency of syllables and length of buzzes in songs contain information on male quality and competitive ability and are correlated with reproductive success (Voigt et al. 2008).

### Social Integration

Social integration signals are used to facilitate social cohesion predominantly among group mates and kin or between parents and offspring. One feature that is common to social integration signals across species is that they have either an individual or group signature (i.e., each individual or group has a relatively unique signal). The majority of these calls are long and tonal with frequency modulations that are unique to the individual or group. The most widespread social integration signals in bats and indeed most mammals are termed infant *isolation calls*. Young bats go through a non-volant period where, in the majority of species, mothers leave their pups behind while they forage and must find and identify their pup among others in the roost site upon their return. Infants produce isolation calls, and in some species mothers produce maternal directive calls to facilitate reunions. In at least one species, *Phyllostomus discolor*, vocal learning plays a role in the development of maternal directives (Esser 1994, reviewed in Knoernschild 2014; Vernes 2017). As in many other mammals, mothers can discriminate among isolation calls from different pups and respond preferentially to their own offspring. Females can rapidly track and update their template of infant isolation calls, as these rapidly change during ontogeny (reviewed in Gillam and Fenton 2016).

The second main category of social integration calls are *contact calls* that serve to identify and recruit group mates and/or family members (beyond just mother/pup reunions). In a number of species, bats have individual- or group-specific calls that allow bats to identify and join group members within roost sites often while bats are returning from foraging. For example, Spix's disc-winged bats (*Thyroptera tricolor*), which roost in furled leaves that require constant roost switching, produce group-specific calls from roost sites that are then "answered" by flying bats looking for the roost (reviewed in Bohn and Gillam 2018; Gillam and Fenton 2016). Vocal communication is particularly important in species where cooperation is common particularly among non-kin (see review Wilkinson et al. 2016). For example, in greater spear-nosed bats (*Phyllostomus hastatus*), bats learn social group-specific social calls to coordinate foraging and cooperatively defend food sites from other groups (Boughman 1998), and in common vampire bats (*Desmodus rotundus*) where bats cooperate via reciprocal blood sharing, bats identify conspecifics using contact calls and during playback experiments preferentially responded to previous blood donors more than kin (Carter and Wilkinson 2016).

### Neurobiology of Acoustic Communication

Although vocal learning is relatively rare among mammals apart from humans, at least three species of microchiropterans from distinct evolutionary lineages show evidence of vocal adaptation/learning of communication signals in social contexts, making them a compelling taxon for investigating the neurobiology of vocal production and perception (reviewed in Knoernschild 2014; Salles et al. 2019; Vernes 2017). Echolocation requires constant real-time audiovocal feedback, which may provide a basis for the evolution of social modification of communication signals.

Different areas of the brain of bats have been implicated on the control of vocalization production. Communication or echolocation vocalization can be elicited from bats when different regions of the brain are stimulated, either electrically or chemically. The periaqueductal gray

(PAG) and the amygdala may be necessary in the production pathway of social communication.

The neuronal processes involved in the decoding of the semantic content of different types of vocalizations have yet to be fully understood. Some communication calls may share commonalities with echolocation sounds, such as signal duration and bandwidth, which makes neural discrimination of species-specific calls by the bat brain a challenge. Several brain areas appear to play a role in the discrimination of communication and echolocation calls, and these regions include the amygdala, the auditory cortex, and the inferior colliculus. The brain of bats appears capable of successfully interpreting the content of social vocalizations, regardless of spectrotemporal overlap with echolocation calls (reviewed in Salles et al. 2019).

### Olfactory Communication

Bats, being nocturnal, are expected to rely heavily on olfaction in addition to acoustic signals. There is very little research on chemical signals in bats, especially when compared with acoustic communication (reviewed in Dechmann and Safi 2005). The common presence of specialized glands for pheromone production supports its role in communication. However, while most mammals use specialized vomeronasal organs and accessory olfactory bulbs specifically for pheromonal communication, the majority of bats appear to have lost this ability (Yohe et al. 2017). Experiments in the laboratory on a number of species have shown that bats can use scent to identify roost mates from unfamiliar bats or individuals. Olfaction is also used in parent-offspring recognition in addition to isolation calls. Chemical signals are especially important in mate selection. For example, males of many molossid and phyllostomid species have *gular glands*, large glands on their throats that produce compounds applied to roosting surfaces or conspecifics. Male emballonurid species have wing sacs where they deposit secretions, and in the singing *S. bilineata*, they wafted odors toward females while performing wing-flapping displays. Research has shown that chemical signals can

provide information on identity, sex, reproductive condition and status.

### Visual Communication

Microchiropteran bats are nocturnal and usually roost in dark areas, making vision constrained and nearly impossible for communication depending on the roosting habitat of the species. Multiple species perform visual displays, particularly those that roost in lighted areas, like *S. bilineata* that roost on the sides of trees in the neotropics or wing-flapping displays in *T. brasiliensis* that commonly roost under bridges. For most bats, their appearance usually mimics their roosting environment, with reddish, brown, or black fur; and there does not seem to be a strong sexual dimorphism in most species. Only few species have facial colorations including yellow and white pigments that may have a function in communication (see Chaverri et al. 2018); however, whether they are used in communication is not well understood.

### Tactile Communication

Tactile communication occurs in affiliative behaviors as it requires close contact. These types of interactions often happen in roosts and are mediated by fur and different types of touch receptors common in mammals. Some bats also have specialized hairs called vibrissae that are present in the muzzle and, in some species, feet that gather precise information about the tactile surroundings of the animal. The most common form of tactile communication is social grooming. Licking, rubbing, and scratching a conspecific may carry information regarding identity, health, and status. Most microchiropteran bats will huddle when roosting, reinforcing social bonds within colonies.

## MicroRNA

Akash Mallick

Centre for Chemical Biology, CSIR-Indian Institute of Chemical Technology, Hyderabad, Telangana, India

## Definition

MicroRNAs or miRNAs are small noncoding RNAs, which regulate gene expression at post-transcriptional level through RNA-protein interactions and thus influential for varieties of biological processes.

## Introduction

MicroRNAs (miRNAs) are small, functional non-coding RNAs of ~22 nucleotides – which are integral part of gene expression regulation at post-transcriptional level. They are involved in a wide array of biological processes such as cellular growth, proliferation, and differentiation and other fine-tuned developmental processes (Ameres and Zamore 2013). Such small RNAs were first discovered in *Caenorhabditis elegans* while finding the role of *lin-4* in postembryonic cell lineage formation. Interestingly it was found that *lin-4* does not code for any protein but represses *lin-14* expression for proper lineage progression. Surprisingly, nothing much could be deciphered except the fact that both of them share high degree of sequence complementarity (Lee et al. 1993). Genome-wide studies based on computational analysis showed huge variability in

their number from very few in sponges to more than 1,500 in humans (Ameres and Zamore 2013). Apart from this, *in silico* studies also indicated that they can target more than half of the protein-coding genes in human and in turn can regulate their function, which possibly evoked through evolutionary selection pressure (Friedman et al. 2009). Therefore, miRNA dysfunction is also associated with various human diseases including cancer.

## Biogenesis of miRNAs

Both biogenesis and mode of action of miRNAs are well-coordinated and cumulative interplay of RNA and proteins (especially **Argonaute** family proteins). miRNAs are derived from longer double-stranded RNAs which are cleaved and trimmed to form mature and functional ones through sequential steps. Much longer, double-stranded RNA (intramolecular) called primary miRNA (pri-miRNA) starts the proceedings for biogenesis, which is trimmed and processed sequentially by RNase III enzyme (e.g., Drosha, Pasha) and dsRNA-binding proteins (Lee et al. 2003). Similar to regular transcription, pri-miRNAs are also produced by RNA Pol II from distinct miRNA-coding transcriptional unit as well as introns of the protein-coding genes (Lee et al. 2004). Then **Drosha** as a part of ~600 kDa complex along with another heterodimeric protein complex called **DGCR8** (in mammals) or **Pasha** (in other animals) cleaves the stem-loop structure of the pri-miRNA at their base to produce ~60-nucleotide-long pre-miRNA at the nucleus. Because of the polycistronic organization of the miRNA genes, multiple pre-miRNAs can be produced from a single pri-miRNA (Kim et al. 2009; Denli et al. 2004). Further processing of pre-miRNA occurs at the cytoplasm, which necessarily requires transport of the pre-miRNA from the nucleus to cytoplasm – mediated by a Ran GTP-dependent double-strand binding protein **Exportin5**. In the cytoplasm, another RNase III enzyme called **Dicer** does further processing of pre-miRNA into ~22-nucleotide-long duplex with the help of **TRBP** (transactivation response RNA-

binding protein) and **PACT** (protein kinase R-activating protein) in mammals and **Loquacious** in *Drosophila*. In flies, miRNAs are generated by **Dicer 1**, whereas **Dicer 2** is associated with siRNA biogenesis, but in mammals, single **Dicer** does so. AGO proteins are then loaded into miRNA duplex in association with chaperone machinery to form pre-RISC (RNA-induced silencing complex). AGO does the final trimming of the miRNA duplex to produce “seed sequence” – which provides specificity for target mRNA 3' UTR (Ameres and Zamore 2013).

*Seed sequence:* Generation of “seed sequence” is very essential for miRNA function as it provides the high affinity binding with target mRNA and thus provides target specificity. Any mutation or alteration in seed sequence results in disruption of repressive activity of a particular miRNA. Structural and functional analysis of AGO proteins throughout plant and animal kingdom, including archea and bacteria, shows impeccable impact of seed sequence modification by AGO proteins. Structural and ITC (isothermal titration calorimetry)-based studies revealed that AGO does structural rearrangement of the seed sequence for stronger affinity with target sequence via their PIWI/MID domain through reduction of entropic penalty (Wee et al. 2012; Parker et al. 2009).

*Self-regulation of miRNAs:* Amplitude of miRNA-mediated mRNA repression is fine-tuned by directing bound miRNA destruction. Studies on miRNA degradation in fly and mammals showed that target mRNA itself induces miRNA destruction following binding to their complimentary sites, in order to restrict particular miRNA – which shows cooperative mode of regulation. Such destructive action involves trimming (3'-5' exonucleolytic resection) as well as tailing (addition of A or U) of the miRNA. However, clear and detail mechanisms including involvement of additional proteins are still a matter of research. On the other hand, such destructive action is exclusive in miRNA pathway in *Drosophila*, but not in the case of siRNA. siRNA in flies can escape this action because **HEN1** (HUA enhancer 1) cannot introduce 2'-*O*-methylation of the seed sequence while AGO1

loading. In flies, siRNA pathway is mediated by AGO2, and thus HEN1 cannot exert such action – thus such distinctive regulation can do self- and non-self-recognition too (Ameres et al. 2010).

*isomiRs*: As miRNA-mediated repression depends on the seed sequence, sequence heterogeneity at seed sequence can provide more diverse target range. Small RNA sequence-based studies on diverse group of organisms including tissues and cell types have provided astonishing dimension of miRNA diversity via generation of isoforms of miRNAs – referred as *isomiRs*. Such isomers can be generated due to improper trimming or dicing of pri-/pre-miRNA including further addition of nucleotides. Alteration in 5' end of the miRNA is an efficient way of making *isomiRs* as 5' end defines the target signature. Such editing can be a result of adenosine deamination via ADAR (adenosine deaminase acting on RNA) – which can also edit dsRNAs (Kawahar et al. 2007). Surprisingly in *Drosophila melanogaster*, 3' trimming is profoundly observed in Ago1-bound miRNAs irrespective of the source of the pre-miRNA. But this process requires another protein called nibbler which has 3'–5' exonuclease activity. Following Ago1 loading, Nibbler does so to fit the miRNA in the PAZ domain of Ago1 and in turn come up with heterogeneity. Apart from this, 3' heterogeneity can also arise due to addition of extra nucleotides commonly referred as tailing. TNTases (terminal nucleotidyl transferase) exerts such tailing via 3' uridylation of the miRNA (Liu et al. 2011).

*RISC formation and target destruction*: Mature miRNAs exert their functional impact of posttranscriptional gene silencing via formation of **RISC** (RNA-induced silencing complex) in collaboration with *Argonaute* family proteins and their associated partners via perfect or imperfect base pairing with the target transcripts followed by catalytic activity of the Ago proteins or additional functions of recruited partners (Ameres and Zamore 2013). Several repressive strategies including decapping, deadenylation and 5'–3' mRNA degradation, and translational repression are utilized by RISC either singly or in combinations. Ribosome profiling and genome-wide miRNA-mediated repressive studies showed that

target mRNA decay is the dominant form of repressive strategy (66–90%) in comparison with translational repression (6–26%) in mammalian cells. miRNA utilizes same indigenous 5'–3' mRNA decay machinery for the target mRNA degradation. During this process, **PAN2-PAN3** along with **CCR4-NOT** deadenylase complex causes deadenylation of the target mRNA, followed by decapping through **DCP2** (decapping protein 2) along with additional partners like **DCP1**, **EDC3** (enhancer of decapping3), **EDC4** (**Dcp1** *Drosophila melanogaster*), **DDX6**, and **PATL1**. Finally, cytoplasmic nuclease **XRN1** (5'–3' exoribonuclease 1) degrades the deadenylated and decapped target mRNA (66). Besides this, **GW182** family proteins {having multiple tryptophan (W) containing motifs} interact with Ago family proteins and deadenylase complexes to assist the degradation pathway (Ameres and Zamore 2013; Jonas and Izaurralde 2015).

Besides robust and more effective mRNA degradation-mediated repression of mRNA, translational repression is also another strategy used by miRNAs. This process is a much weaker one and found during early expression of miRNAs. Artificial mRNA reporter-based assay showed that such mode of repression can be independent of mRNA decay pathway and also helpful for those mRNAs which do not possess distinctive poly A tail and are resistant to deadenylation (Mathonnet et al. 2007).

*Multiple targeting by single miRNA*: As miRNA utilizes 3' UTR of the target mRNA and imperfect pairing of seed is sufficient to exert the repressive action, thus single miRNA can target multiple genes simultaneously. For example, miRNA-200b can regulate cell motility and cell invasion via targeting of cytoskeletal genes at multiple levels as well as by regulating structures called focal adhesion and invadopodia. Conversely, multiple miRNAs can regulate common biological processes as found in regulation of actin cytoskeleton by miR-200 family. Surprisingly, such miRNAs are produced from polycistronic clusters and thus act as cooperative functional unit of miRNAs. Similar to multi-strategic action of miRNAs, mRNA 3' UTR also

restricts robust action of miRNAs. Specially functioned genes produce mRNA with longer 3' UTR with higher density of miRNA target sites as compared to housekeeping genes – thus provides further prominent landscape of regulation evolutionarily (Bracken et al. 2014).

miRNA-mediated repression can be indirect as they can target downstream effector of a gene or even downstream transcription factors to mediate indirect action. Typically miR-200 family exerts such effects in regulation of EMT, where such miRNAs target EMT regulator ZEB1 and SNAIL1 to control EMT indirectly (Perdigão-Henriques et al. 2016).

Till now miRNA has shown their role in mRNA repression either directly or indirectly, but they can be linked to gene activation also. miRNA-mediated gene activation is an indirect mode of activation where repression of the repressor of certain genes can result in activation of particular gene as found in neuronal differentiation of vertebrate groups. miR-128 has found to do so for neuronal differentiation and proper brain function (Bruno et al. 2011).

So, miRNA has enormously wide landscape of function and strategy to fine-tune different biological processes. Despite our detail knowledge about their structure and mode of action, still newer areas are there to be open.

## Microsatellite Marker

Rahul Kumar

International Centre for Genetic Engineering and Biotechnology, New Delhi, India

Neurobiology Division, Defence Institute of Physiology and Allied Science (DIPAS), Defence Research and Development Organisation, Delhi, India

Pharmacology and Toxicology Department, National Institute of Pharmaceutical Education and Research, Hyderabad, India

## Synonyms

Short tandem repeats (STR); Simple sequence repeats (SSR)

## Definition

Microsatellites are very short nucleotide (two to seven) sequences repeated many times, number of repetition varying depend on the type of species which is used to determine genetic diversity, paternity studies, and population studies in identification of genetic traits and also in forensic studies.

## Introduction

The term “microsatellite” was first of all given by Litt and Luty (1989). A microsatellite is a region of the repetitive DNA sequence localized in both prokaryote's and eukaryote's genome. The length of the microsatellite marker is one to six base pair and is repeated, typically 5–50 times. Additionally, microsatellites are found in thousands of the location in the whole genome of the organism. The rate of mutation in the microsatellite marker is very high as compared to other region of the genome or DNA. Microsatellite markers are also known as simple sequence repeats (SSR), short tandem repeats (STR), and

simple sequence length polymorphisms (SSLP), which are found in both prokaryotic and eukaryotic organisms.

## Location and Structure of Microsatellite

They are widely distributed throughout the genome, especially in the transcriptionally active region, i.e., euchromatin of eukaryotic genome as well as coding and noncoding nuclear and organelle DNA (Pérez-Jiménez et al. 2013; Phumichai et al. 2015). Additionally, they are located at noncoding as well as regulatory site of coding region of genome. However, microsatellites of the noncoding regions have not been explored yet; these noncoding regions lead to accumulation of mutation that are involve in the formation of variation from one generation to another generation which use in DNA finger printing. Microsatellite mutation at the regulatory region of coding region leads to phenotypic changes and diseases like fragile X syndrome and Huntington's disease.

## Features of Microsatellite Marker

- Microsatellites are repeated mono-, di-, tri-, tetra-, and pentanucleotide unit sequence which are widely distributed in genome (Powell et al. 1996).
- They are found in the genome of both prokaryotes and eukaryotes.
- They are also found in organelle genome such as mitochondria and chloroplast (Powell et al. 1995).
- These are widely distributed throughout the genome with high rate of mutation as compared to other regions of genome. The mutation rates estimated in the microsatellite marker range between  $10^{-4}$  and  $10^{-2}$  per generation.
- The microsatellite region in genome leads to high diversity.
- They are most potentially powerful informative molecular marker with easily operated and low cost PCR analysis.

## Origin of Microsatellite

The origin of microsatellite marker in genome can be nonrandom and take place due to the imbalance between the processes that promote microsatellite formation and the process that prevent microsatellite initiation. At present, there are two non-mutual exclusive hypotheses to explain the origin of microsatellite.

- (i) **De novo microsatellite:** According to this hypothesis proposed by Messier et al. (1996), the origin of microsatellites was a consequence of creation of proto-microsatellites, a short region with three or four repeated units. Proto-microsatellites originate by the base substitution or indel events and latter supported by observation that insertions tend to copy adjacent bases (Gemmell 2006). Once proto-microsatellite is initiated, its maintenance and multiplication is favored by its tendency to undergo strand slippage during replication.
- (ii) **Adopted microsatellites:** According to this hypothesis proposed by Wilder and Hollocher (2001), the origin of microsatellites was from the other region of genome through transposable elements. These transposable elements composed of two or more than two site which is involve in microsatellite formation. Transposable element is a DNA sequence that can move from its position within a genome that lead to creating or reversing mutation and later the cell genome identity as well genome size.

## Type of Microsatellite Markers

Many authors classified marker according to the presence of nucleotide bases: short repeats (30 nucleotides) are microsatellite marker and long repeats (10–100 nucleotides) are minisatellite markers. Moreover, microsatellite marker is further classified according to the type of repeat sequence present.

- (a) **Perfect microsatellite marker**, when sequence show only perfect repetitions, e.g., (AT)<sub>20</sub>
- (b) **Imperfect microsatellite marker**, when repeated sequence interrupted by different nucleotides which are not further repeated, e.g., (AT)<sub>12</sub>GC(AT)<sub>8</sub>
- (c) **Composite microsatellite marker**, when there are two or more than two different repeats motif present in *tandem*, e.g., (AT)<sub>7</sub>(GC)<sub>6</sub>

However, the composite marker has been categorized as both perfect and imperfect microsatellite marker. The di, tri, and tetra repeated nucleotide sequences are most commonly used in molecular genetic studies (Selkoe and Toonen 2006).

## Application of the Microsatellite Marker

From the last few years, microsatellite marker has been used in the characterization screening and to appraise the genetic diversity between the different species.

- I. **Forensic lab studies:** From the last few decades, microsatellites have become a very powerful technique in the forensic studies. It has been used as genetic fingerprinting for the differentiation of individual of the same species. The microsatellite's principle is based on the analysis of all tetra- and pentanucleotide repeat and it gives high degree of error-free data. Shorter repeat sequence has a tendency to suffer from artifacts such as PCR shutter as well as several genetic diseases that are associated with trinucleotide repeat such as Huntington's disease (Angel Carracedo 2010).
- II. **Population genetic study:** Microsatellite markers were also useful in population genetics study during the 1990s. It became ubiquitous in research laboratories. This study, based on the PCR, allowed researchers to design primers and analyzed set of microsatellites at minimum cost (Manel et al.

2003). Microsatellite marker are also applicable for interfering or measuring bottlenecks, population size gene flow, all allelic fixation index, and local adaptation.

III. **Conservation biology:** Microsatellite markers are crucial tool to analyze the rapid change, effect of population fragmentation, and interaction of the different population. It is also used in the identification of incipient and new population. Additionally, there markers are also useful to identify adaptation of population in new environment condition.

IV. **Genome mapping:** It is a very important technique which helps in mapping the genome as well as in identification of the location of the significant portion in the genome. Additionally, they are also widely applicable in the area of publicized human genome mapping (Moxon et al. 1999).

V. **Cancer detection:** In cancer cells, the rate of microsatellite expansion (increase in the number of repeats) and microsatellite contraction (decrease in the number of repeats) increases due to defect in the enzyme that is involved in the correction of the copy DNA. Initial clinical detection of some type of colon and bladder cancer has been successfully identified by the use of the alteration in microsatellite repeats (Yonekura et al. 2002).

VI. **Biological/evolutionary context:** Microsatellite markers are also used to address the degree of relatedness between the individual and groups. In case of endangered or captive species, microsatellite is used as a tool to evaluate the level of inbreeding. Microsatellite marker is used to admission the demographic history (e.g., to look for evidence of population bottlenecks), and to access the effective population size as well as the direction of the gene flow between population. They are also used for fine-scale phylogenies up to the level of closely related species.

VII. **Diagnosis and identification of human disease:** Microsatellite markers are also widely used as marker in the biomedical diagnosis of the certain disease. Microsatellite alleles are also associated with the occurrences of mutation in the coding region of DNA that

lead to variety of disease. Microsatellite is associated with change in length of the early development of cancer. Therefore, it is used as a marker for diagnosis of early cancer. These markers have polymorphic nature; therefore, they are useful in linkage studies which attempt to identify the location of the genes responsible for various disorders (Kashi and Soller 1999).

There are some examples of diseases associated with microsatellites trinucleotide repeats (<http://www.woodrow.org/teachers/esi/2002/biology/projects/p3/diseases.htm>).

### Limitations of Microsatellite Markers

Even though microsatellites have many advantages over other molecular markers, all data sets might include some errors and genotyping errors remain a subject in population genetics because they might bias the final conclusions (Bonin et al. 2004). Microsatellite genotyping errors result from many variables (reagent quality, Taq polymerase error, or contamination), as reviewed by Pompanon et al. (2005).

- (a) Null alleles: Mutation or deletion of locus in the annealing primer inhibits heterozygous identification and locus amplification that leads to inaccurate estimation of allele segregation and frequency rates.
- (b) Homoplasmy alleles: Alleles identical in state (length) but not by descent are homoplasic alleles. They can be identical in length but not in sequence with different evolutionary history (Anmarkrud et al. 2008). Because homoplasmy is disregarded, the actual divergence between populations is underestimated. Sequencing could be used to identify differences in sequences, but differences in evolutionary history can only be identified by mutations documented in known pedigrees.
- (c) Linkage disequilibrium: It is deviations from the random association of alleles in a population, which are primarily caused by population substructuring and high levels of

| S. no | Name of the disease            | Symptoms of the disease                                                                                                                                                                                                                      | Involvement of microsatellite                                                                                                                                                                                                                                                |
|-------|--------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 1.    | Huntington's disease           | Late onset dementia and loss of motor control, motor disorder accompanied by the loss of memory or cognitive deficit, juvenile onset is rare, patient show rigidity, epilepsy and severe dementia                                            | Occurs due to alteration in CAG coding repeat in the first exon of HD gene. Normal gene is composed of 6–36 repeats and affected gene is composed of 36–121 repeats. The microsatellite adds a string of glutamine amino acid to the Huntington protein (Bailer et al. 2002) |
| 2.    | Fragile X                      | Mental retardation, long and prominent ears and jaws, high-pitched speech, Hyperactivity, poor eye contact, and stereotypic hand movements                                                                                                   | The repeat is CGG in a noncoding region of the FMR2 gene. Normally this gene is composed of 6–53 repeats and the affected gene is composed between 60 and 200 repeats                                                                                                        |
| 3.    | Myotonic dystrophy             | Involving hypotonia, respiratory distress at birth, and developmental abnormalities. Adult onset. Includes variable loss of mental function, myotonia, muscle weakness, and progressive muscle wasting                                       | It involves CTG repeats in a noncoding region of the DMPK gene. Normal gene is composed between 5 and 37 and the affected gene may involve 50–1000 repeats                                                                                                                   |
| 4.    | Spinal bulbar muscular atrophy | Neurological degeneration associated with difficulties in speech, articulation and swallowing, muscle weakness and atrophy Signs of mild androgen insensitivity are typically seen at adolescence                                            | It involves CAG repeat in the first coding exon of the androgen receptor (AR) gene. Between 9 and 36 repeats is normal, and people with 38–62 repeats develop the disease                                                                                                    |
| 5.    | Friedrich's ataxia             | Ataxia, diminished tendon reflexes, loss of position and vibratory senses, dysarthria (slurred speech), cardiomyopathy, diabetes mellitus, optical atrophy, scoliosis, and skeletal abnormalities. Age of onset is typically early childhood | It involves GAA repeat in noncoding region of gene X25. Normal gene contains between 7 and 34 repeats. The disease gene has 34–80 repeats (Santos et al. 2010)                                                                                                               |

inbreeding (Weising et al. 2005). It is especially problematic for population studies and paternal exclusion. This problem could be detected by the computer programs or an offspring analysis.

exchangeable data format to allow users to access different kinds of analyses and computer programs easily (Excoffier and Heckel 2006) and the best understanding about microsatellite evolution and mutation mechanisms.

## Perspectives

The application of microsatellite markers has been validated by a large number of studies and different areas that apply microsatellite for different purposes. Additionally, novel technologies have allowed the improvement of markers for previously neglected species over the generation of new sequences and a more developed search in databases. However, there are some bottlenecks that need to be overcome as they hamper the best and widespread use of SSR data, e.g., an

## Conclusion

Over the last few decades, the use of molecular marker has been playing a vital role in the analysis of genetic diversity and genetics. Out of the different types of molecular marker, microsatellite marker has been extensively used because they can be easily amplified by PCR and also used in the analysis of large amount of the genetic variation (allelic variation at each locus). Microsatellite markers are simple sequence repeats and typically composed of one to six nucleotide repeats. These

markers are abundant and distributed throughout the genome. Microsatellite markers are highly polymorphic as compared to the other molecular markers as well as species specific and codominant. Due to this, microsatellite markers have become increasingly important genetic markers in the amplification of genetic diversity, population genetics, and disease diagnosis. This scenario confirms the current relevance of microsatellite marker and indicates their continuous utilization in different studies.

## Introduction

The cause of migration is specific for each individual or group of individuals. Some migrate

in search of food, and some migrate to avoid unfavorable climatic conditions such as extreme cold and hot conditions, etc., while others migrate to carry out their reproductive functions such as searching mate, spawning, etc. Migration occurs in response to some internal and external cues – external cues include photoperiod, food/water availability, changing seasons, earth's magnetic field, etc., while internal cues include low fat reserves, circadian rhythms, etc. Apart from the external cues, some portions of the migratory mechanism have a genetic basis. Variations in migratory phenotype are observed in migrants within the same species as well as in closely related species, and these variations are genetically and epigenetically controlled. However, the genetic and epigenetic control mechanisms are not well understood and are still under investigation. Diadromous and catadromous migrations occur through water, while some migrations occur through drift carried out by wind, current, etc.

Migration allows migrants to exploit a greater range of resources and to use the favorable environmental factors present in a different environment to their own advantage for survival and greater reproductive success but also has a great effect on communities and ecosystems. Migrations result in competitions for resources between migrants and local inhabitants which sometimes lead to scarcity of resources in that particular zone. Migration exerts top-down effects on residents by affecting predation pressure. The migrants often increase the predation risks for the nonmigrants in their absence. The migrants also act as vectors for diseases and carry these diseases to the new environment thereby affecting the communities. Migration also helps in transfer of genetic information and affects the gene pool. It has been seen that migration has the capability to enhance and weaken community stability. Even the effect of migration on nutrient cycles and primary productivity in ecosystems is worth mentioning.

Various forms of migrations are seen in animals, and these are categorized on the basis of the organism, space, time, as well as the medium through which the movement takes place. The various types of migration include the

following: obligatory, a regular, consistent, and predictable migration; facultative, an optional migration in response to specific conditions; partial, when some individuals migrate while others remain in the breeding area; differential, when migratory differences are seen in individuals based on age and sex; to-and-fro, migration of animals between two areas; round trip/loop, when migrants return to their breeding ground passing through succession of non-breeding areas; one-way, when migrants are translocated from their native environment to another where they breed and produce successive generations before dying; altitudinal, migration from lower altitudes and higher altitudes; vertical, migration between different zones of water bodies; nomadic, an irregular migration linking temporary breeding sites which host suitable conditions; seasonal, long-distance migrations on a seasonal basis; and irruptive, when portions of population migrates while other members remain on their breeding.

The earliest documented observation on migration was that by Aristotle who noticed that the birds around him changed with season and concluded that a species gave rise to the other with change of season. Others noted that birds disappeared in winter and probably hibernated deep down the earth. With time and careful scientific observation, these earlier explanations gave way to a deeper understanding of the fact that migration is widespread in the animal kingdom and has basically emerged as a mode of survival (Lohmann 2018).

## Definition

In a general sense, the word migration refers to the movement of biological entities from one place to another with specific motives or due to some external or internal influence. However, migration in ethology and ecology refers to the large-scale movement of individual animal or animal groups to a different environment. This movement may be cyclical, frequently occurring, and sometimes on a daily basis, and the reason of migration also varies in different species. Most animals migrate to avoid

unfavorable conditions and to enjoy better opportunities with respect to food availability, less competition, safety from predators, better reproductive success, and utilization of necessary resources. The complex nature of animal migration due to its variability in different animal groups (birds, mammals, fishes, insects, etc.) makes the process difficult to explain. One of the commonly used definition is migratory behavior defined as “persistent and straightened out movement effected by the animal’s own locomotory exertions or by its active embarkation upon a vehicle. It depends on some temporary inhibition of station keeping responses but promotes their eventual disinhibition and recurrence.” The fact that migration mainly occurs seasonally and is followed by a return journey distinguishes it from other types of animal movements including emigration.

In a strict sense, the term migration encompasses four distinctive but overlapping concepts: (i) a tenacious locomotory practice; (ii) a resettlement of an animal which is an outcome of longer periods of movement excluding those which are a part of daily routine; (iii) a seasonal to-and-fro movement of populations between regions hosting alternately deleterious or beneficial conditions, including the breeding ground; and (iv) movements leading to redistribution within a spatially extended population. These concepts include the various components of migration of individuals as well as of populations such as cause of migration, cues of migration, types of migrations, and its effects on the ecosystem.

## General Description

Migration is the movement of animals from one place to another. The main reason an animal hibernates or migrates is due to the lack of food, which occurs during the winter months due to the cold weather. In contrast hibernation is when animals rest or remain asleep during the entire winter. Hibernation and migration are adaptations for animals to survive winter months when food is not available.

There are different kinds of hibernation. Some animals sleep so deeply, they are impossible to wake up, like the woodchuck and bat. Some of them are light sleepers like raccoons, skunks, and opossums that wake up during the winter to eat. Many bears take long rests and also lightly sleep during the winter months.

Animals also migrate to other areas during the winter months. Many birds fly long distances to escape the cold winter, like the Arctic tern from the North Pole that flies South to Antarctica. Some birds in the far south of South America, Australia, and Africa migrate to the North, and others from east to west to coastal climates. The monarch butterfly travels south during the winter where there are flowers. A few animals must avoid the extreme heat, so they migrate to cooler areas. Animals may also migrate to find a good habitat to raise their young ([softschools.com](http://softschools.com) 2018)

## Types of Migration

Migration is the movement of people from one place to live in another. Emigrants leave their country, while immigrants enter a country. Migration impacts on both the place left behind and on the place where migrants settle. People have many reasons why they might want to move from one place to another. These reasons may be economic, social, political, or environmental. For migration to take place, there are usually push factors and pull factors at work. Push factors are the reasons that make someone decide to move. This is their own experience of life in one place which gives them good reasons to leave it.

There are different types of migration such as counter-urbanization, emigration, immigration, internal migration, international migration, and rural-urban migration.

## Factors Influencing Migration

### In Birds

All birds do not migrate, but all species are subject to periodical movements of varying extent. The

birds which live in northern part of the hemisphere have greatest migratory power.

Migration may be:

- (i) Latitudinal
- (ii) Longitudinal
- (iii) Altitudinal or vertical
- (iv) Partial
- (v) Total
- (vi) Vagrant or irregular
- (vii) Seasonal
- (viii) Diurnal
- (ix) Nocturnal

**Latitudinal migration:** The latitudinal migration usually means the movement from north to south and vice versa. Most birds live in the land masses of the northern temperate and subarctic zones where they get facilities for nesting and feeding during summer. They move towards south during winter.

An opposite but lesser movement also occurs in the southern hemisphere when the seasons are changed. Cuckoo breeds in India and spends the summer at Southeast Africa and thus covers a distance of about 7250 km.

**Longitudinal migration:** The longitudinal migration occurs when the birds migrate from east to west and vice versa. Starlings (*Sturnus vulgaris*), a resident of east Europe and West Asia, migrate towards the Atlantic coast. California gulls, a resident and breed in Utah, migrate westward to winter in the Pacific coast.

**Altitudinal migration:** The altitudinal migration occurs in mountainous regions. Many birds inhabiting the mountain peaks migrate to lowlands during winter. Golden plover (*Pluvialis*) starts from Arctic tundra and goes up to the plains of Argentina covering a distance of 11,250 km.

Birds migrate either in flocks or in pairs. Swallows and storks migrate a distance of 9650 km from northern Europe to South Africa. Ruff breeds at Siberia and travels to Great Britain, Africa, India, and Ceylon thus traveling a distance of 9650 kms.

**Partial migration:** All the members of a group of birds do not take part in migration. Only several

members of a group take part in migration. Blue jays of Canada and northern part of United States travel southwards to blend with the sedentary populations of the Southern United States of the USA Coots and spoonbills (*Platalea*) of our country may be an example of partial migration.

**Total migration:** When all the members of a species take part in the migration, it is called total migration.

**Vagrant or irregular migration:** When some of the birds disperse to a short or long distance for safety and food, it is called vagrant or irregular migration. Herons may be an example of vagrant or irregular migration. Other examples are black stork (*Ciconia nigra*), glossy ibis (*Plegadis falcinellus*), spotted eagle (*Aquila clanga*), and bee-eater (*Merops apiaster*).

**Daily migration:** Some birds make daily journey from their nests by the influence of environmental factors such as temperature, light, and humidity also. Examples are crows, herons, and starlings.

**Seasonal migration:** Some birds migrate at different seasons of the year for food or breeding, called seasonal migration, e.g., cuckoos, swifts, swallows, etc. They migrate from the south to the north during summer. These birds are called summer visitors. Again there are some birds like snow bunting, red wing, shore lark, gray plover, etc. which migrate from north to south during winter. They are called winter visitors.

## In Fishes

**Migratory pattern in Chinook salmon fish:** It is the largest of the Pacific salmon and has black spots on its tail and the upper half of its body. They have black pigment along the base of teeth. The weight (pounds) of largest Chinook documented is about 126 pounds.

**Distribution:** In the western Pacific, the distribution ranges from northern Japan in the south to the Arctic ocean.

**Classification:**

Kingdom: Animalia  
 Phylum: Chordata  
 Class: Actinopterygii  
 Order: Salmoniformes

Genus: *Oncorhynchus*

Species: *O. tshawytscha*

Fish status: Nine populations of Chinook salmon are listed under the US Endangered Species Act as either threatened or endangered.

Type of migratory fish: These fishes are anadromous meaning they are born in freshwater, migrate to sea, and return to freshwater to spawn.

Migration: Homing instinct is strongest among salmons and generation after generation. They return to the same river. The Chinook salmon provides a legendary example of this homing instinct. Every year, countless millions of salmon carry out one of the greatest animal migration on earth. The longest and most remarkable of these journeys runs the entire length of the Yukon River by Chinook fishes across interior Alaska and into northwestern Canada.

Beginning of migration: The Yukon River Chinook migrates upstream during the fall of a distance of about 2,000 in miles.

The first migration: Chinook spend a full year in the Yukon River before migrating to the first summer, building up enough fat to carry them through the long boreal winter. The little Chinooks now begin their first great journey – swimming and drifting downstream, urged by the current.

Life in the ocean: As they grow; juvenile Chinooks move into the northern. The Bering Sea ranges from about 60 degrees latitude up through the Bering Strait.

The second migration: In the second migration, a king salmon heading back to its home river cover a tremendous distance – perhaps a thousand miles or more.

Some experts speculate that salmon might use the position of the sun or its polarized light as a compass.

Biologists also have known that a salmon has flecks of magnetite in its snout, so possibly it uses the earth's magnetic field as a compass.

Migratory pattern in European eel: The European eel is a species of eel, a snake-like fish.

Distribution: The European eel inhabits the Atlantic Ocean from Europe to North America.

This eel is native to the Atlantic Ocean off the coast of Europe.

Classification:

Kingdom: Animalia

Phylum: Chordata

Class: Actinopterygii

Order: Anguilliformes

Genus: *Anguilla*

Species: *A. anguilla*

Fish status: The European eel is a critically endangered species.

Migratory pattern: These fishes are catadromous, those migrating from freshwater to the sea for spawning.

Migration: The spawning migration of the European eel to the Sargasso Sea is one of the greatest animal migrations. Adult European eels begin their spawning migration from European rivers and coasts during the autumn of each year [predominantly October to December] and must migrate a distance of between 5,000 and 10,000 km (depending on their departure locations) to presumed spawning area in the Sargasso Sea.

### Migratory Behavior

**Vertical Migrations** Eels that reached oceanic depths exhibited a stereotypical vertical migration, moving from shallow water between night and day. Vertical migration resettled in a diel temperature change with experienced temperature being cooler during the day than at night. Eels released from Swedish west coast and the Baltic outlet experienced extreme ambient temperature below 0 °C, whereas eels released from the Celtic Sea (Ireland) rarely experienced temperature lower than 9 °C.

### Migration Route

It has been observed that migration routes are not simply error-free great-circle routes (i.e., the shortest possible route to the Sargasso Sea from the departure points); instead many of the routes are in the reverse direction of the northern part of the subtropical gyre in the Northern Atlantic Ocean which is consistent with the hypothesis

that eels follow olfactory cues originating in the spawning areas or that eels navigate using oceanic cues imprinted or learned during the leptocephalus phase.

**Migration speed:** The speed of migration was estimated in European eels about 37 km per day.

**Migratory pattern in carps:** Carps are various types of oily freshwater fish which belongs to the family Cyprinidae which are found in abundance native to Europe and Asian subcontinents. Most cyprinid forms have scales and teeth on the inferior pharyngeal bones which may be modified in relation to the diet.

**Distribution:** The various species of carps (common carp, *Cyprinus carpio*, etc.) is widespread freshwater fish of eutrophic waters in lakes and large rivers in Europe and Asia. Several species of carps are considered invasive in the USA and worldwide, and large sums of money are spent on carp control.

**Classification:**

Kingdom: Animalia  
Phylum: Chordata  
Class: Actinopterygii  
Order: Cypriniformes  
Family: Cyprinidae  
Genus: *Cyprinus*  
Species: *C. carpio*

**Fish status:** IUCN Red List status has listed the common carp under the vulnerable category.

**Migratory pattern:** These fishes are potadromous because these fishes move and complete their life cycle entirely within freshwater.

**Migration:** Potadromous fishes exhibit complex life cycles and habitat use pattern that are integrated with the diversity of their various life stages and associated body sizes. The migratory behavior in carps arises from spatial, seasonal, and ontogenetic separation of optimal habitats for growth, survival, and reproduction.

Schlosser in 1991 described the basic migrations of stream fishes among three types of habitat (feeding, overwintering, and spawning).

After hatching, most carps migrate during each of the four subsequent mobile life stages (larvae,

juvenile, subadult, and adult). The diversity of destination habitat and movement patterns by carps in riverine and lacustrine system reflect seasonal habitat preferences as well as shifts in preferred habitats as fishes develop among life stages. After larval fish emerge, some may drift passively with stream or lake currents. Others may begin feeding, even before their yolk sac is absorbed.

After fish attain the juvenile stage, the diversity of movement may further increase, if there is an abundant food supply, if cover is adequate (i.e., water depth, overhead cover), and if other rearing conditions are favorable like temperature and move within that range until winter.

**Distance range of migration:** Migration and movement of carps range from short distances approximately 1–2 m to long distance >650 km.

#### Migratory Pattern in Atlantic Herrings

**Description:** Atlantic herring is a herring in the family Clupeidae. It is one of the most abundant fish species in the world. Atlantic herring can be found on both sides of Atlantic oceans congregating in large schools.

Atlantic herring have a fusiform body. Atlantic herrings are in general fragile. They have large and delicate gill surfaces, and contact with foreign matter can strip away their large scales.

**Distribution:** Atlantic herrings can be found on both sides of the ocean. They range across North Atlantic waters such as the Gulf of Maine, the North Sea, Irish Sea, etc.

**Classification:**

Kingdom: Animalia  
Phylum: Chordata  
Class: Actinopterygii  
Order: Clupeiformes  
Family: Clupeidae  
Genus: *Clupea*  
Species: *C. harengus*

**Conservation Status:** Least Concern (LC)

**Migratory pattern:** Herring species are anadromous, traveling up coastal river to spawn. Atlantic herrings are fully marine and migrate to coastal and offshore spawning grounds. In late summer

and early fall, Atlantic herrings aggregate into massive schools and move into coastal water at various rotations in the Gulf of Maine to spawn. They also spawn on offshore bank such as the Georges Bank and Brown Bank south of Nova Scotia. Spawning times vary for different populations of Atlantic herrings.

**Migration:** Herrings are small fishes, the adults being about 25–30 cm in length. Baltic herrings are smaller and somewhat larger. They mature at about 3 or 4 years of age, and their annual fecundity amounts to 40,000–10,000 eggs. They live and swim in large shoals, each of which may be many kilometers across. They migrate towards the surface at night and then tend to disperse in shoals. They make long migration each year from spawning ground to feeding ground and back and have to travel distances of up to 2000 km to do this; they usually swim down tide or current. The herrings of any spawning group spawn at the same season each year to within about a week.

In the North Sea, there are two autumn spawning stocks, Buchan and Dogger, in the northern and central North Sea and a winter spawning stock, the Downs, in the south of the North Sea. The North Sea herring migrate in a clockwise circuit in the North Sea.

In general, the spawning pattern of herring conforms to the typical triangular migration pattern common in pelagic schooling. Adult fishes migrate against currents from feeding ground to spawning grounds. Larvae drift passively away with currents, and juveniles eventually swim back out to join adults at feeding grounds.

**Factors in human:** Many people choose to migrate. These are voluntary migrants. Many are economic migrants. Other voluntary migrants include older dependents who want to live somewhere warm and sunny in their retirement. However many other people have no choice and are forced to leave their homes. These are involuntary migrants. Their lives and homes may be in danger due to war or a natural disaster. These people are also called refugees.

**Importance of migration in humans:** Often push factors are negative things such as unemployment, crop failure, droughts, flooding, war, poor education opportunities, or poor services and

amenities. Pull factors, on the other hand, are the expectations which attract people to the new place. They are usually positive things such as job opportunities, a better standard of living, better education, or better healthcare. Push factors are the reasons that make someone decide to move. This is their own experience of life in one place which gives them good reasons to leave it. Often push factors are negative things such as unemployment, crop failure, droughts, flooding, war, poor education opportunities or poor services and amenities. Pull factors, on the other hand, are the expectations which attract people to the new place. They are usually positive things such as job opportunities, a better standard of living, better education or better healthcare.

**Evolutionary significance of migration:** Migration in animals significantly contributes towards selective advantages leading to evolution of species. Although migration in birds have been more fascinating and widely studied, migration is a phenomenon widely present across species which include insects, fishes, amphibians, as well as mammals. Migration is an adaptive response integrated with the survival needs for less competition, ambient temperature, avoidance of harsh weather conditions, and availability of resources. It is also critically associated with the need to find the right geographical conditions that support breeding. The process and consequence of migration have considerable evolutionary significance. For example, migrating population of birds lack information on the weather/environmental condition at destination and utilize length of day as a guiding mechanism. Length of day helps these birds adjust the timing, intensity, and choice of place for migration and breeding. Photoperiodic response of migratory birds pre-determines juvenile development and expression of reproductive features (Coppack and Pulido 2004). This ability to respond to daylight may be completely lacking in birds that do not depend on photoperiodic response for food or other survival mechanism.

Migration is also a common feature in fishes, although less explored compared to their avian counterparts. Young salmon migrate to the sea to take advantage of abundant food but returns to

rocky tributaries to spawn (Dingle 2014). It has been observed that migratory species are better adapted to utilize available resources and grow faster but may sexually mature later compared to nonmigratory species (Roff 1988).

Genetic variation in migratory vs non-migratory population is an important factor leading to evolution of species better adjusted to the prevalent environmental conditions. Due to high energy demands and exposure to varied pathogens during migration, certain genes related to higher innate immune response may be favored and expressed. If the migrating population ends up mating with the residents, this brings greater variability in the gene pool. Any favorable combination will be selected, thriving genetic drift and emergence of a population genetically different from the original species.

**Methods of studying migration:** Migration is a complex behavioral phenomenon that has several other associated factors such as genetics, physiological, biomechanical, ecological, and evolutionary aspects. Hence scientific study of migration demands a broad and integrative approach that includes empirical and theoretical approach. This section of the chapter will focus on some of the current methodologies employed in the study of migration.

**Field method** – This method employs direct counting of birds/animals as spotted in a particular area or field which could be a natural landmark in the path of migration or a man-made object. This method has been popularly used to study bird migration but also has been employed to study butterflies and other organisms. Although this method can lead to detail information on the population and their relationship with the environment, this can be very time-consuming and not a cost-efficient method (Boccagni and Schrooten 2018).

**Tracking method** – Migrating animals have been studied by tracking them down their migratory path. Tracking employs extrinsic and intrinsic markers present in the animals. Extrinsic markers uses capture-recapture/resighting data where animals are captured and data collected on their unique recognition markers and released only to be recaptured at a different geographical

location to validate its migration. This method heavily depends on the number of sites at which data is being collected. It also depends on animal behavior and use of the site. Natural markers have been successfully used to distinguish migrants from residents and identify the link between migrating population at either ends of route and the source of migration. Some natural markers used are footprints in large terrestrial animals and head and plumage details in birds. Song dialect in birds, e.g., the white crowned sparrow (*Zonotrichia leucophrys*), has also been used to separate migrants from residents (Milligan and Verner 1971). Man-made markers such as the use of metal rings have also been employed to study migration in birds for more than 100 years, and the ring recovery data has been compiled in bird migration atlases. Satellite tracking through radio transmitters has greatly revolutionized this method of studying migration using external markers; however radio transmitters can only be used on relatively large animals. The smallest transmitter is about 10gm which restricts the use of transmitters on animals weighing 250 gm or above. This criterion alone excludes about 80% of world's birds and 70% of mammals. The fundamental flaw in the use of extrinsic markers to study migratory animals is that it can be employed only on marked individuals and the probability of their recapture/resighting (Dingle 2014).

Intrinsic markers have great advantage in understanding the migratory path and migration in animals as these markers are integrated tissue features in the animals. Measure of stable isotopes of hydrogen (H), oxygen (O), nitrogen (N), carbon (C), and sulfur (S) has routinely been used to study migration particularly in aquatic or airborne animals. Stable isotopes are like footprints of where the animal has been and a unique tool in the study of migration. The isotopes are records of the dietary sources of animals, and provided a database of environment specific isotope is available, the migratory path of the animals can be easily tracked. The O and H isotopes are geographically preserved and are related to the hydrological and meteorological over thousands of years for a particular geographical region,

hence enabling interpolation of regional isotope data. The “hydrogen cycle” and the measure of H isotope composition are used to evaluate the migratory path in aquatic animals. Various processes in water cycle lead to large-scale geographic patterns of hydrogen isotopes in water, which can be quantitatively used to study migration. The choice of food available to the migrating animals offer unique composition of stable isotope that is integrated in the body and can be biochemically analyzed from small tissue samples to identify the geographic pathway of migration. Two types of tissue samples are usually used to measure stable isotopes. The first type is fixed tissue that is metabolically and hence isotopically inert. This includes keratinous materials such as feathers, claws, nails, hair, etc. Metabolically and isotopically inert tissue materials are used to determine the local environment where the tissue was initially formed (Coiffait et al. 2009). However, caution should be exerted while analyzing slowly growing keratinous tissue. Feathers and claws that grow slowly as the animal migrates will incorporate isotopes from the diet of the animal en route and therefore may show a variation in isotope composition. The second type of tissue sample used is dynamic and metabolically active and directly depends on the dietary habit of the migrating animal. The samples are blood, muscles, organ tissue, and even feces. The turnover rate for isotopes varies a few days in the blood and liver, weeks in the muscle, and lifetime in bone collagen. A comprehensive manual for sampling wild birds has been documented by Whitworth, et al. (2007) and needs to be particularly referred when dealing with highly pathogenic avian influenza (HPAI).

**Radiotelemetry** – Radiotelemetry is a powerful tool to study migration in animals that move in air or in aquatic environment and surface to breathe. This method employs attaching a device either externally (noninvasive) or implanted in the body of the migrating animal (Hay and Nebel 2012). Signals from the device can then be collected to understand the pattern and pathway of migration. Ambient temperature of the environment the migrant is in and even water pressure for aquatic animals. In addition, physiological

information of the migrating animal, such as rate of wing beat in birds, respiration rate, heart rate, etc., can also be accessed using radiotelemetric devices. Choice of device may vary depending on the environment and the range of movement of the migrating animal. Radio transmitters are typically used to collect long-distance signal transmissions, whereas ultrasonic devices are normally used for short-range transmissions (Bowlin et al. 2005; Leon et al. 2004; Wolcott 1995). Currently the ocean tracking network with its headquarter at Dalhousie University, Canada, is monitoring movements of more than 150 species of aquatic animals around the globe. International cooperation for animal research using space (ICARUS) is another organization that aims to develop a telemetric system based on low-orbiting satellites in order to track numerous migratory species (Dingle 2014). The biggest hurdle in the use of radiotelemetric method of migration study is the impact on energy budget and the size requirement of the devices. An ideal radiotelemetric device should not exceed 2–5% of the total body mass of the animal. Most often, the devices fail due to small-sized battery dying out or because the transmitter was destroyed due to the fact that the animal was either hunted or harvested. As such the researcher can never track down the reason for device failure without tracking down the animal.

## Conclusion

Migration is classically defined as the regular movement of animals each year between separate breeding and wintering grounds. There are many different types of migratory behavior, ranging from completely sedentary populations to populations that are completely migratory (obligate migrants). There are three kinds of natural selection that can cause evolutionary change: directional selection, disruptive selection, and stabilizing selection. The study of Darwin’s finches illustrates how rapidly natural selection can result in a change in phenotype. Homeostasis is an important mechanism for maintaining internal balance. In achieving homeostasis,

animals maintain a relatively constant internal environment even when the external environment changes significantly. Birds use both internal maps and compasses to find their way during migration. Olfactory maps and magnetic maps are believed to help birds locate themselves in space. Three internal compasses allow birds to sense the direction in which they are flying. These are the sun compass, the star compass, and the magnetic compass. The fishes also show potential migratory patterns with special reference to their change in habitats. The mechanisms used by different organisms to orientate during migration are still largely unknown and are currently the subject of ongoing research.

## Mimicry

Gisela Kaplan  
School of Science and Technology,  
University of New England,  
Armidale, NSW, Australia

Mimicry as an inherited adaptation is very widespread and can be found even at molecular level, mimicking viral antigens (Rose and Mackay 2000; Shahrizaila and Yuki 2010). Some plants and flowers display visual mimicry (van der Niet et al. 2011; Lev-Yadun 2017). Among insects (Lepidoptera), the butterflies and moths offer

plentiful examples of mimicry of colors and patterns. The large group of invertebrates with exoskeletons from scorpions, crabs, and others to spiders (Herberstein and Wignall 2011), grasshoppers, and even cockroaches (Vršanský et al. 2018) furnish examples of mimicry. Fishes (Randall 2005), octopi (Norman et al. 2001; Gómez-Moreno 2019), and other creatures in the seas may mimic by supplementing colors and patterns with species-typical movements (usually locomotion patterns) of other, more dangerous species. Mimicry of most forms, be this visual or olfactory, is absent in mammals, but there are other land vertebrates such as lizards, frogs (Rojas 2017), and even snakes, in which such mimicry is present.

Mimicry is thus an important biological phenomenon that occurs for a number of reasons. In general, it may enable undetected invasion as is possible in some predatory wasps or spiders that invade ants' nests by means of mimicry of ant pheromones or body shape in order to gain access to food (Allan et al. 2002; Malcicka et al. 2015). Mimicry may be a method of self-protection for an otherwise defenceless organism by adopting the colors or patterns of another species. The ones being mimicked are most often unpalatable or even toxic, and the more convincing the mimicry, the greater the protection from potential predators. Adaptive mimicry of shape and color

thus tends to be protective (Krajewski et al. 2004) and, in some contexts, may provide safer or the only access to a food source (Pereira et al. 2013).

The mimics have no direct way of making themselves more or less camouflaged. It is a permanent mimicry that is genetically inscribed and thus adaptive. There are many variations and shades to such bodily mimicry – in some, the mimicry is not all too convincing (sparingly defended prey species), while in other cases, the mimicking animals may be very well-camouflaged by having taken on rather accurate markings and shapes of their toxic counterparts (Fig. 1).

Mimicry, as H. Bates originally argued in the nineteenth century, involves three parties: the true identity of the species being mimicked; the mimicker; and the predator that is deceived by the mimicker and will not eat it because it looks like the unpalatable model (Wickler 1968). Müllerian mimicry formulated usually involves at least two parties, both of which are unpalatable or toxic. The two share common predators and mimic each other to their mutual benefit, leading to the predator's avoidance of both (Sherratt 2008).

Adaptive signals of mimicry are not confined to visual signals. Some species utilize the recipients' ability to perceive vibrations, scents, or flashing lights that can serve equally well to

M

**Mimicry, Fig. 1** Left, monarch butterfly (*Danaus plexippus*); right, viceroy butterfly, (*Limenitis archippus*), both of North America. Note their similarity in color and patterns. These two species were often cited as classic Batesian mimicry adaptations (the harmless viceroy

mimicking the toxic monarch butterfly). However, the viceroy is now known to be poisonous too, giving each butterfly twice the protection from predators; thus are examples of Mullerian mimicry

deceive, i.e., stop potential predators from eating them, but the mimicry can also be used to attract potential partners either as honest courtship signals or to be deceptive in order to attract potential prey.

In fishes and invertebrates in the sea, such as salmon (Weir et al. 2016), sunfish (Rios-Cardenas and Webster 2008), peacock blenny (Gonçalves et al. 2003), squid (Hanlon et al. (2002), and many others, it is relatively common to find so-called sneaker males that are not only substantially smaller but mimic females and often succeed precisely because they are perceived by the dominant male as constituting no direct and immediate threat.

### Vocal Mimicry in Birds

Sound signals from different species or between male and female can be or become convergent or more similar. This may be an indication of a - well-tuned and well-matched pair, as, for instance, in magpie-larks, *Grallina cyanoleuca* (Hall and Magrath (2007). They duet, and these duets may overlap, but usually the calls of two birds follow each other closely and are so very similar and so precisely timed that apart from physical distance

of the two birds (and possible localization of different sound sources), they may sound like the vocalizations of one bird. This is called convergence, not mimicry.

Vocal mimicry is not convergence of sounds within its own species and its own vocal repertoire. Unlike mimicry of shape, color, and/or patterns, vocal mimicry does not exist as part of the species' own specific repertoire but only as a potential capacity. Mimicked sound signals are thus in a class of their own. As long as they are produced via the syrinx (not air sacs or wings), such sound signals have to be learned. The ability to produce identifiably mimicked sounds is one that each bird has to learn and acquire individually. For physiological and other reasons, some songbirds may not be able to mimic another bird very well (such as frequency range), but, in general, mimicry of another bird or even of mammals (dog barks, horse neighing, and of human speech) may be surprisingly accurate (Kelley and Healy 2011; Kaplan 2000, 2015).

The ability to mimic tends to exist only in songbird species that are lifelong learners and are able to integrate new sounds into their own repertoire at any time in their adult lives (unlike songbirds with fixed song learning periods and crystallized song, as in the zebra finch) (Fig. 2).

**Mimicry, Fig. 2** Sonograms: (a) one element of the loud and noisy typical kookaburra “laugh” and (b) the magpie’s rendition. Although the magpie’s own song is largely tonal and melodious, the bird successfully rendered the noisy

quality of the sound (gray fuzzy) and its loudness (energy to 5 kHz). Australian magpies, *Gymnorhina tibicen*, are among the most accomplished Australian songbird mimics, apart from lyrebirds (see also Kaplan 2000)

In general, vocal mimicry in birds could be regarded as a paradox. Vocal behavior in birds is species-specific and identifies a species, while any mimicry blurs or contradicts species identification (Hausberger et al. 1991).

According to Goller and Shizuka (2018), vocal mimicry is widespread among songbirds and parrots but perhaps not as widespread as was once thought. Goller and Shizuka identified 339 species out of their sample of 4,410 songbirds. Importantly, unlike the mimics of color and patterns in a wide variety of non-vertebrates and some vertebrates, vocal mimicry is not a stable behavioral attribute. It apparently evolved independently at least 237 times and was lost at least 52 times (Goller and Shizuka 2018).

### Functions of Vocal Mimicry

In animal behavior one expects to be able to identify functions that serve the species in its survival. Vocal mimicry, however, extends over a wide range of different functions, some of which may be adaptive (Baylis 1982), while others have no obvious function, and there is little consistency across species. Some parasitizing cuckoo chicks learn to approximate the food-begging calls of the host chicks, as do channel-billed cuckoos (imitating nestling currawongs and magpies; Kaplan 2015). This has also been evident in common cuckoo chicks raised by various warblers (Butchart et al. 2003). The ability of these cuckoo chicks to approximate the food-begging calls of the species raising them may well have survival value, and thus it is an adaptive behavior.

When birds mimic their own parents or members of their group, accuracy about a specific sound profile may ensure vocal recognition and also facilitate and enhance communication within groups (Wheatcroft and Price 2013).

Another type of mimicry is connected with territoriality. Birds may copy sounds of neighbors of the same species (Putland et al. 2006). Territorial birds tend to share part of their repertoire with permanent neighbors.

In the above cited contexts, the mimicked sequences are still part of the natural repertoire even if partly adopting a neighbors' set of sounds. In the latter context, it is thought that sharing repertoire reduces competition between neighbors, but such sharing can also be deceptive in certain circumstances (Wilson and Vehrencamp 2001).

Other examples of mimicry in the wild are reported cases of pink cockatoos raised by galahs adopting the vocalizations of their host parents (Rowley and Chapman 1986). The African grey parrot also mimics in the wild (Cruickshank et al. 1993), furnishing at least some anecdotal evidence that parrot mimicry is not just an artifact of captivity and of living in human company (Fig. 3).

Particularly in lyrebirds, mimicry is used as embellishment in the male's courtship display. It can involve calls and song sequence of other avian species, sometimes even sounds of mammals or inanimate objects, the purpose being to make the song more attractive for a female to choose the courting male over other males.

**Mimicry, Fig. 3** Red-lored parrot, *Amazona autumnalis*, of Central and South America may be one of the few cases of mimicry observed in the wild (pers. observation in Guatemala)

## Vocal Mimicry and Cognition

The cognitively interesting aspects of vocal mimicry, be they short or relatively long, demonstrate very clearly that vocal mimicry is the result of learned behavior. In human babies, the acquisition of human speech also begins with mimicry that is constantly socially shaped by parents who give signals of strong social approval when babblings such as “mamama” eventually turn into “mama,” meaning that syllables are beginning to be shaped into words. In a study of juvenile magpie babblings, it was found that the stages of vocal development match human babbling stages (Kaplan 2017). As in human babbling, the sounds produced are initially not intentional, but, in human social contexts, the mimicry gradually turns into socially meaningful words.

Vocal mimicry in birds was said not to have reached the stage of sounds developing into independent (no longer mimicked) stable and identifiable signals (language). In birds, vocal mimicry is said to remain just that: mimicry. As has been shown above, even such mimicry can be used to deceive and thus be an intentional act. Moreover, this has been proved incorrect in some instances of wild, untrained songbirds. In one case, an Australian magpie had learned to call a dog at the very moment when a cat approached the bird, roosting on a tree trunk in a hostile manner. Instead of fleeing, the bird called the dog by name. On being called, the dog came running chasing the cat away (Kaplan 2019). The magpie’s calling signifies a new context for the mimicked name and represents an intentional act. The interaction between cat/dog/magpie suggests that the bird had learned to associate the word/sound not just with a specific animal but that the word could call in help. Cognitively, this is quite a complex process.

In another context, African drongos had learned alarm calls of other species in order to frighten groups of birds away and then access the bounty of flying insects (Munn 1986). Similar reports aiding the acquisition of food resources

**Mimicry, Fig. 4** The fork-tailed drongo, *Dicrurus adsimilis*, furnishes one of the best and most complex examples of mimicry. Their varied deceptive alarm calls make other species flee and leave behind valuable food sources for drongos to exploit (Attis 1979, Creative Commons/Wikipedia)

have also been reported in great tits (Møller 1988; Satischandra et al. 2010) (Fig. 4).

The fork-tailed drongo of South America even varies deceptive mimicked alarm calls so that other birds are tricked every time. It causes them to flee while the mimicking bird is able to collect and even steal food (Flower et al. 2014). Clearly, vocal mimicry can reflect not just learning ability but additional cognitive abilities if such mimicry is effectively applied in new situations. Both adaptive and vocal mimicry continue therefore to be of great interest to science. The latest discoveries suggest that both, adaptive and cognitive mimicry, have long evolutionary trajectories and still produce surprising and novel applications and contexts.

### What Is Miniaturization?

Miniaturization represents a morphological phenomenon that leads to the extreme body reduction of a lineage in comparison to a non-miniaturized and larger ancestral (Hanken and Wake 1993). This phenomenon has independently evolved several times among metazoans, including several vertebrate and invertebrate lineages (Hanken and Wake 1993; Hedges 2008; Weitzman and Vari 1988). The evolution of such a reduced body size is associated with dramatic changes in anatomy, ecology, and physiology for the lineages (Hanken and Wake 1993), most likely favoring and/or increasing the lineage fitness, for instance, the occupation of new niches, to explore new food resources, to avoid predators, to reduce intra- and interspecific competition, and to promote rapid reproductive maturity (Hanken and Wake 1993).

Miniaturization might be especially common in certain environments (Hanken and Wake 1993), and the fact that several of the smallest and largest animals are found in islands has historically raised

the attention of several biologists. This curious phenomenon is known as “the island rule” (Van Valen 1973) and depicts the traditional scenario in which large animals tend to become smaller (=insular dwarfism), and small animals tend to be larger (=insular gigantism) on islands. For instance, most of the smallest vertebrates in the world are island inhabitants (e.g., Glaw et al. 2021; Hedges 2008; Ocampo et al. 2018; Rittmeyer et al. 2012). Even though there has been a long debate whether such a trend applies to all vertebrates, insular dwarfism might be, in most cases, a result of taxa miniaturization, most likely associated with natural selection forces toward an optimal size (Van Valen 1973).

As miniaturization occurs in very different ways in vertebrates and invertebrates, this entry will address this phenomenon for the former group. When applicable, data for invertebrates will be included as examples.

## The Lowest Limits of Size

Given the wide diversity of metazoan body plans, it is not simple to establish an absolute value for the lowest size of an animal. While several invertebrate phyla might attain microscopic sizes, vertebrates with the lowest sizes reach an average body size of about 7–35 mm (Kottelat et al. 2006; Rittmeyer et al. 2012). Extremely reduced body sizes in ectotherm vertebrates include, for instance, the fish genus, *Paedocypris*, with a total mean length of 7.9 mm; the frog *Paedophryne amauensis*, with a mean of 7.7 mm (Rittmeyer et al. 2012); the hummingbird of Cuba (total length of about 64 mm, *Mellisuga helenae* Ocampo et al. 2018); the snake *Tetracheilostoma bilineata* (total length of about 100 mm; Hedges 2008); and the lizard, *Brookesia nana* (total length of about 21 mm; Glaw et al. 2021). Extreme size reduction seems to occur more drastically in ectotherms and is directly associated with body energetic demands.

Decrease of the body size also involves structural modifications to maintain functional efficiency at a strongly reduced size (Hanken and Wake 1993; Rieppel 1996). The reduction in

body size is associated with a change of structural proportions and may lead to the transformation of structures that are possibly attained by the reduction of tissue cell layers and/or reduction of cell volume (Rensch 1948). However, there is a minimum critical size that the species can reach in order not to impair its biological functions, such as feeding, locomotion, and reproduction (Hanken and Wake 1993; Rieppel 1996), with such a lower limit being constrained by the maximum volume that organs can fill in the body cavity (Rensch 1948). For instance, the number of clutch size and egg shape seem to be constrained by the extreme reduction of the miniaturized snake *Tetracheilostoma carlae* (Hedges 2008). In this species, the clutch size is of one, a result of the tradeoff between clutch size and relative offspring size, in combination with the tubular body shape of snakes (Hedges 2008). Such a tradeoff seems to also occur in other small-sized snake species (Hedges 2008).

## Morphological Consequences of Miniaturization

Miniaturization is rather much more than attaining a very reduced size (Hanken and Wake 1993). Besides evaluating the general morphological alterations that occur in miniaturized lineages, the phylogenetic position of such miniaturized clades must be evaluated to distinguish derived characters that were a result of miniaturization, from synapomorphies that precede the size reduction (Pérez-Ben et al. 2018). Three general consequences of miniaturization have been previously identified for tetrapods, although it might sometimes be applied to other metazoans: (i) structural simplification or reduction; (ii) emergence of morphological novelties; and (iii) increased intraspecific morphological variation (Hanken and Wake 1993).

Structural simplification or structural reduction is one of the best documented consequences of miniaturization among metazoans, being associated with the reduction or complete loss of organs and/or systems (Hanken and Wake 1993; Rieppel 1996). In vertebrates, for instance, these

consequences have been identified in the loss of several skull and appendicular skeleton elements (Rieppel 1996). Most morphological simplifications and reductions are associated with the skull because it houses several fundamental organs for the organism survival, such as the brain, inner ear, and eyes, and must not decrease in size beyond a specific limit (Hanken and Wake 1993; Rieppel 1996).

The emergence of morphological novelties is intimately associated with size decrease and seem to compensate for the reduction of organs and/or systems of vital function (Hanken and Wake 1993). This consequence is widespread among vertebrates and invertebrates, with the emergence of several remarkable structures, such as hyperossified skulls, the subcephalic copulatory organ of phallostethid fishes, and the ciliated wings of a few beetles (Hanken and Wake 1993; Yeh 2002). Osteological novelties among tetrapods are highly variable; however, miniaturized lineages of tetrapods are known for their proportionally large sense organs and their skeletal elements (Rieppel 1996). These changes might be a result of the conservative negative allometry between the brain, eyes and otic capsules in vertebrates, as well as the constraints imposed on nervous and sensory systems to maintain functional efficiency even at a small-sized head. Given such alterations, the skull (mostly the braincase) must go through an extensive “packaging effect” due to the need for spatial arrangement to maintain fundamental skeletal functions such as feeding (Rieppel 1996).

Increased morphological variability within species is the third morphological consequence of miniaturization, being a direct result of the reduction or morphological novelty of the lineage. Among vertebrates, it is usually associated with late-development skeletal structures, leading to variations that may occur intra-individually or within a population (Hanken and Wake 1993). Such an evolutionary consequence has been thoroughly detailed for the salamander of the genus *Thorius* (Hanken and Wake 1993), with the presence/absence of elements such as the septomaxillary bone.

## The Role of Heterochrony in Miniaturization

Miniaturization has been historically associated with the developmental consequences of heterochrony, which can be defined as changes in the rate or timing of developmental events over evolutionary time (Gould 1977; Hanken and Wake 1993). Two main heterochronic phenotypes are associated with miniaturization: (i) paedomorphism and (ii) peramorphism (Gould 1977; Hanken and Wake 1993; Rieppel 1996).

Paedomorphism occurs when later stages of ontogeny of an organism retain characteristics of earlier stages of development of its ancestor (Gould 1977). Such characteristics might be retained due to the truncation of growth period (known as progenesis), by the decrease of the growth rate (neoteny) or by a delayed onset of developmental processes (postdisplacement; Gould 1977). In this sense, it seems that elements that appear in later stages of ontogeny suffer greater variation in miniaturized species if compared to the ones that emerge earlier (Hanken and Wake 1993). Some examples include the loss or extreme simplification of skull elements in anurans, the reduction of number of digits in salamanders (Hanken and Wake 1993), loss of skull and post-cranial elements/simplification in Squamata (Rieppel 1996), the loss of cranial crests in mammals (Rieppel 1996), and the distinct skeletal morphology in a few fish species (Britz et al. 2009). For instance, skull bones that are frequently lost in miniaturized anurans – palatines, columellae, and quadratojugals – are among the last to ossify in frogs, being consistent with paedomorphosis (Yeh 2002). However, paedomorphosis is not necessarily strictly correlated to the miniaturization of a lineage and might be independently responsible for the generation of morphological novelties and simplifications (e.g., Pérez-Ben et al. 2018). For instance, this phenomenon might have been fundamental in generating the avian skull bauplan with large brains and to enable beak elongation and cranial kinesis along with the evolution of the lineage (Bhullar et al. 2016).

On the other hand, peramorphic organisms exhibit developmental processes that extend beyond the developmental stages of their ancestral lineage, producing adults with exaggerated characteristics (Gould 1977; Hanken and Wake 1993). Some examples include the hyperossified skull of a few lizards (e.g., Daza et al. 2008) and anurans (Paluh et al. 2020). These exaggerated characteristics play an important role in the generation of morphological novelties, one of the main consequences of miniaturization. On the other hand, peramorphism might also act to generate large body sizes, as its fundamental role in the evolution of multiple fossil lineages including non-avian dinosaurs (Foth et al. 2016), and to the general bauplan of the avian skull (Plateau and Foth 2020).

## Miniaturization in Vertebrates

Miniaturization is extensive and well-documented for several major vertebrate clades, such as fishes (e.g., Weitzman and Vari 1988), amphibians (e.g., Hanken and Wake 1993), lizards (e.g., Glaw et al. 2021), snakes (e.g., Rieppel 1996;), birds (e.g., Ocampo et al. 2018), and mammals (e.g., Rowe 2020). Indeed, this phenomenon has been historically hypothesized as a key feature in the evolution of many major taxa among vertebrates, including snakes (Rieppel 1996), lissamphibians (but see Pérez-Ben et al. 2018), birds (Lee et al. 2014), and mammals (Rowe 2020), as well as the origin of several morphological simplifications, as the simple anatomy of the lung in the first amniotes (Lambertz et al. 2015), and also by favoring the evolution of endothermy in the theropod lineage leading to birds (Rezende et al. 2020). However, as the endothermic metabolism of birds and mammals dictates a larger minimum adult body size compared to ectotherms, consequently, miniaturization is more common – and certainly more extreme – in fishes, amphibians, and reptiles (Hanken and Wake 1993).

Miniaturization has independently occurred several times along fishes evolution, being a common phenomenon among teleosts, with such a group exhibiting several examples of the

reduction, structural simplification, morphological novelties (e.g., hyperossification), and increased morphological variability (Weitzman and Vari 1988; Hanken and Wake 1993; Britz et al. 2009). While larger fishes seem to occur in marine environments, smaller lineages – specially miniatures – are most likely to occur (but not exclusively) in more complex environments, such as the South American streams (Weitzman and Vari 1988). For instance, representatives of the genus *Paedocypris*, a cyprinid fish of about ~10 mm long, is one of the smallest vertebrates currently known (Britz and Kottelat 2008). This lineage exhibits a number of unique specializations that consists of a mixture of truncated characters resembling larval stages of other members from the family, as well as several novel autapomorphic features, as a hypertrophied genital papilla in males that are most likely consistent with their extreme miniaturization (Britz and Kottelat 2008). Indeed, as *Paedocypris* spp., other freshwater fishes (e.g., *Danionella dracula*; Britz et al. 2009), specially characiforms and siluriforms, represent a model for the study of the evolution of miniaturization in the group (Britz et al. 2009; Weitzman and Vari 1988). However, the phenomenon of miniaturization might occur under poor environmental conditions, pushing the population to rapid miniaturization. For instance, recent studies (e.g., Esin et al. 2020) have detected paedomorphic miniaturization in a population of cyprinid fishes (*Salvelinus malma*) as an adaptation of volcanic impact, with the occurrence of changes in the lifestyles, physiological characteristics, shortening of lifespan, and anatomical simplification in the expressive short period of about 25 years. Thus, under the volcanic impact, the species attained, through paedomorphic miniaturization, an evolutionary mechanism that enabled the successful reproductive cycle under high risks (Esin et al. 2020).

As fishes, amphibians represent the group with best documented processes that result from miniaturization (Hanken and Wake 1993). This phenomenon has figured in discussions of the evolution of the three extant amphibian orders from their much larger temnospondyl ancestors, although such a phenomenon has been recently

unrelated to their evolution (but see Pérez-Ben et al. 2018). Despite that, several instances of miniaturization have occurred in salamanders – as the genus *Thorius* (Hanken and Wake 1993) – in several lineages of anurans (Yeh 2002), and caecilians (Hanken and Wake 1993) with several morphological novelties, variation and the reduction or digit loss, and/or simplification of the skull and nervous system (Hanken and Wake 1993). Among amphibians, life history traits are also associated and constrained by miniaturization. For instance, among several miniaturized brachycephalids, leptodactylids, and microhylids, the laryngeal apparatus is highly simplified, clutch sizes are smaller, and miniaturization might have also played an important role in other life history strategies (Estrada and Hedges 1996), as the high incidence of direct development (Rittmeyer et al. 2012; Fig. 1).

Although skull hyperossification has previously been hypothesized as a byproduct of miniaturization in anurans, such a view has recently been rejected for anurans as a whole, with hyperossification most likely representing a peramorphic trait possibly associated with accelerated ontogenetic trajectories and morphological change unrelated to size reduction (see Paluh et al. 2020). However, the relatively large braincase and sensory capsules present in miniaturized anurans seem to indicate that the neurocranium is subject

to a minimum constraint (Paluh et al. 2020) as observed in other vertebrates (Rieppel 1996).

The occurrence of miniaturization among non-avian reptiles is undoubtedly more extensively detailed for squamates – specially for lizards and snakes (Rieppel 1996; Hedges 2008). Even though there are several small-sized lineages of Testudines that have been assigned as miniaturized species (= small taxa in Vlachos and Rabi 2018), recent studies found no direct relation with small size and the phenomenon of miniaturization in these taxa (Angielczyk and Feldman 2013). There seems to be no evident miniaturized living lineage of Crocodylia, although a few extinct taxa exhibit reduced sizes most likely associated with miniaturization (Pinheiro et al. 2013). The most speciose of all miniaturized lizard species is possibly comprised by the species from the genus *Sphaerodactylus*, with miniaturized species exhibiting several morphological novelties/simplification of their skull related to the closure of the post-temporal fossae, reduced skull length and diameter, and bone arrangement (Daza et al. 2008). Among snakes, extreme cases of miniaturization are found in blind snakes, threadsnakes, and worm snakes traditionally known as “Scolecophidia.” Recent works have hypothesized that several characteristics of the group are a result from miniaturization possibly driven by paedomorphosis, including the loss/reduction of

**Miniaturization, Fig. 1** Photos of *Brachycephalus bufonoides* (a) and *B. garbeanus* in life (b). Both species are miniaturized (~12–20 mm of body length in adults) and are restricted to areas of the Atlantic Forest in Brazil. The taxa exhibit several morphological novelties and

simplifications as the hyperossification of their skull, and emergence of new bones in the skull and post-cranial skeleton, and also exhibit direct development. (Photos: J. Perez Pombal Jr)

several skull bones in comparison to alethinophidian snakes (Strong et al. 2020).

Many of the miniaturized living lizards and snakes are found in islands worldwide (e.g., Hedges 2008), leading several authors to associate such a reduction to the island rule phenomena. Additionally, extreme size reduction in these lineages has also been postulated as a direct effect of fossoriality (Hanken and Wake 1993; Rieppel 1996). In such a view, hypotheses suggest that miniaturization represent a consequence of headfirst burrowing, in order to reduce the energy for soil burrowing, therefore generating convergent reinforced skulls with reduced mobility. This might seem the relation for the evolution of such miniaturized body sizes in blind snakes, threadsnakes, and worm snakes traditionally known as “Scoleophidia” (Hedges 2008). Regardless the relation of extreme body reduction to fossoriality, miniaturization in lizards and snakes are reported as structural simplification in the appendicular skeleton as well as morphological novelties in the skull and their associated muscles (Rieppel 1996).

Miniaturization in the lineage of birds is extensively reported for several extinct taxa, being considered as a major event in the origin and diversification of birds in relation to their closest theropod relatives, as well as the possible evolution of arboreality (Lee et al. 2014; Benson 2020). Indeed, many traits that accompanied the reduction of size are associated with developmental truncation, generating, in this lineage, more robust and fused bones, short snouts, enlarged brains and eyes, and smaller teeth (Lee et al. 2014; Benson 2020). However, studies on the miniaturization of living lineages seem to be scarce in the literature. In this lineage, the tiniest bird currently known – the Cuban bee hummingbird, *Mellisuga helenae* – represents a species with several morphological novelties and simplification due to its extreme body size decrease (Ocampo et al. 2018). Hummingbirds, in general, include the smallest species of birds currently known, with the smallest species exhibiting a series of morphological simplifications and novelties, as a lower level of skull ossification, a highly compact skull (Ocampo et al. 2018). These skull traits are a direct result of body and brain size to accommodate disproportionally larger brain and

eyes without the need of increasing overall head size (Ocampo et al. 2018).

Miniaturization represented important milestones for the evolutionary process of mammals, being a key factor for the evolution of endothermy in the group, development of nocturnal habits, and other relevant ecological adaptations as lactation (Rowe 2020). Early mammals might have attained miniaturization by accelerated maturation of the skeleton at smaller sizes, with reduction in size being accompanied by remodeling of the skull and postcranial skeleton (Lautenschlager et al. 2018). For instance, recent studies suggest that the evolution of the mammalian jaw and middle ear are a result of the selective regimes imposed by extremely reduction during the mammaliaform transition (Lautenschlager et al. 2018). Miniaturization has occurred in a few mammal lineages, including rodents, shrews, moles, lemurs, and bats. As very small mammal species have very high mass-specific metabolic rates, miniaturized lineages thus require highly caloric and nutritious food. Therefore, small lineages are associated with highly caloric diets of seeds and insects, with no miniature mammalian species (below 15 g) being strictly herbivorous (Gliwicz and Taylor 2002).

## Definition

The ability to recognize oneself in a mirror.

## Introduction

Mirror self-recognition (MSR), the ability to recognize oneself in a mirror and “the ability to become the object of your own attention” (Gallup 1982, pp. 242–243) is considered to be a reliable indicator that humans and some other animals recognize their reflection in a mirror as an external representation of self (Amsterdam 1972; Anderson 1984; Gallup 1970; Rochat 2003). Researchers have used mirrors as tools to study the development and perception of self in human and nonhuman species. Developmental studies of MSR in humans indicate that the earliest age children first show self-directed behavior is 12–15 months and mark-directed behavior (passing the mark test) first emerges between 18–24 months (Amsterdam 1972; Anderson 1984; Bard et al. 2006; see review in Reiss and Morrison 2017). It has been theorized that proprioceptive awareness may be an antecedent of the onset of MSR and some of the proposed developmental correlates of MSR in children include sensorimotor intelligence, prosocial behavior, synchronic imitation, and pretend play (see review in Reiss and Morrison 2017). In an early paper, Gallup (1982) suggested both an

ontogenetic and phylogenetic link between MSR and empathy. MSR studies have been conducted with a variety of species and most fail to show unequivocal evidence of self-recognition (e.g., squid, manta rays, ants, pigeons, African grey parrots, dogs, horses, sea lions, killer whales, and monkeys) (see a review of some of these studies in Reiss and Morrison 2017).

Only a limited number of nonhuman species have demonstrated MSR: chimpanzees (*Pan troglodytes*), bonobos (*Pan paniscus*), orangutans (*Pongo pygmaeus*), gorillas (*Gorilla gorilla gorilla*), bottlenose dolphins (*Tursiops truncatus*), Asian elephants (*Elephas maximus*), and the Eurasian magpie (*Pica pica*). Most of these species have either large brains and/or higher encephalization quotients (EQ - ratio between actual brain mass & predicted brain mass for an animal of a given size) than species lacking the capacity for MSR (see review in Parker et al. 1994; Reiss and Morrison 2017).

In MSR studies with mirror naïve humans, great apes, dolphins, elephants and magpies, it has been reported that during mirror exposure these phylogenetically divergent species progress through three strikingly similar stages of behavior: (1) social behavior (e.g., reacting as if viewing a conspecific) and mirror exploratory behavior (e.g., attempting to look over, under, or behind the mirror), (2) contingency-testing (e.g., producing repetitive behaviors at the mirror allowing the individual to perceive a corresponding relationship between its own behavior and the mirror image), and (3) self-directed behavior (e.g., viewing parts of their body or monitoring actions they perform that have been previously unobservable in the absence of the mirror) (Amsterdam 1972; Anderson 1984; Bard et al. 2006; Gallup 1970; Morrison and Reiss 2018; Plotnik et al. 2006; Povinelli et al. 1993; Prior et al. 2008; Reiss and Marino 2001).

## MSR in Nonhuman Primates

Gordon Gallup (1970) developed and utilized the first paradigm for testing MSR in nonhuman primates, the mirror test. In this groundbreaking

study, four chimpanzees were exposed to a full-length mirror and their behavior was documented over time. At the start of the study, the chimpanzees vocalized and performed social displays towards the mirror but over time these responses declined and were replaced by self-directed behaviors. Gallup considered the performance of self-directed behavior at the mirror as evidence of MSR in chimpanzees, but created what he considered a more objective experimental procedure, “the mark test,” to further confirm the presence of this ability. The mark test was conducted only after observing self-directed behavior in the chimpanzees (Gallup 1970). The chimpanzees were anesthetized and marked with a red dye devoid of odor or tactile cues above the uppermost portion of their eyebrow ridge and the upper part of the opposite ear, locations that could only be seen when at the mirror. Upon recovery from anesthesia, they were observed for 30 min in the absence of a mirror and then for 30 min when the mirror was reintroduced. The chimpanzees passed the mark test by exhibiting more mark-directed touching in the mirror condition than in the previous condition in which the mirror was absent. In some later studies with great apes, the animals were not anesthetized for the mark test (e.g., Bard et al. 2006; Lin et al. 1992). A similar test, “the rouge test,” was created by Amsterdam (1972) for use in developmental studies with children; however, children are never anesthetized prior to conducting the mark test. Studies with children have used less stringent criteria and passing the rouge/mark test typically requires that the child only touch the mark once or touch their face near the mark without comparing the frequency of touching to that area in the pre-mark condition (Amsterdam 1972; Bard et al. 2006; see review in Reiss and Morrison 2017).

Notably, in past studies with species that have shown the capacity for MSR, not all individuals tested pass the mark test, indicating that caution should be used when assuming that mark test results are the only indicator of MSR. The standard paradigm used in conducting MSR tests with nonhuman species involves exposing an individual to the mirror and only after self-directed behaviors are observed, mark tests are conducted.

Importantly, the performance of self-directed behavior during the period of mirror exposure itself is an indicator of MSR and the mark test is further confirmation (Gallup 1994; Morrison and Reiss 2018; Povinelli et al. 1993; Reiss and Morrison 2017). As previously stated by Gallup (1994),

I have never maintained that the mark test is the *sine qua non* of self-recognition. Appropriate behavior in response to unobtrusively applied facial marks that can only be seen in a mirror constitutes a means of validating impressions that arise out of seeing animals use mirrors in ways that suggest they realize that their behavior is the source of the behavior depicted in the reflection. In trying to demonstrate self-recognition in other species, some people appear to have lost sight of this and have focused almost exclusively on the mark test (p. 42).

MSR has been well documented in all great ape species; however, studies with lesser apes and both old world and new world monkeys have not reported evidence for the spontaneous development of MSR (see reviews in Anderson and Gallup 2015; Reiss and Morrison 2017). Studies of the development of MSR in chimpanzees have reported the ages at which they exhibit social, contingency testing, self-directed and mark directed behavior. Chimpanzees have been observed to exhibit social behavior towards a mirror between 7 and 9 months of age and contingency-testing commenced at about 10 months of age (Robert 1986). Self-directed behavior has been reported to first emerge between 24 months (Bard et al. 2006; Lin et al. 1992) to 3 years, 3 months (de Veer et al. 2002; Povinelli et al. 1993) and mark-directed behavior to be exhibited between 2 years 4 months (Bard et al. 2006; Lin et al. 1992) and 3 years 9 months (de Veer et al. 2002; Povinelli et al. 1993). Different criteria used by Povinelli et al. (1993), de Veer et al. (2002), Lin et al. (1992), and Bard et al. (2006) when judging the performance of self-directed behavior and when determining mark test results may partially explain the discrepancy in age of onset reported in the literature for chimpanzees.

Reports of MSR in ape species led to the speculation and theory that MSR was rooted in common aspects of primate social ecology,

neurobiology, and cognition and led to the assumption and perspective that this ability was confined to humans and their closest relatives, the great apes. However, Gallup (1979) suggested that other large-brained social mammals, such as dolphins, other cetaceans, and elephants that showed empathy (e.g., care-giving, or targeted helping-behavior towards others), would be good candidates to test for MSR.

## MSR in Dolphins

Fifteen years after Gallup's suggestion to conduct mirror tests with dolphins, Marino et al. (1994) conducted a study in which they exposed two mirror naïve 7-year old captive-born, male bottlenose dolphins to a mirror. Gallup's basic procedural approach for testing MSR in apes was used but slightly modified to test the non-handed dolphins that were unable to touch the mark. As in MSR testing with apes, the criteria for demonstrating MSR in dolphins was the demonstration of self-directed behavior during mirror exposure, but the criteria for passing the subsequent mark tests required that the dolphin show mark-directed behavior by orienting its body in a manner that exposed the mark to the mirror. The dolphins remained together during mirror exposure and testing and were marked and tested individually within the social context. During the period of mirror exposure, the dolphins showed evidence of similar stages of behavior as reported in mirror studies with great apes, which was suggestive of MSR. However, the results were inconclusive due to the inability to conduct a sufficient number of mark tests. Each dolphin was only marked once with zinc oxide, a white visible mark, and their adverse reactions to being marked resulted in no further mark tests being conducted. Marten and Psarakos (1994) reported similar suggestive yet inconclusive findings with four out of five dolphins in another test of MSR.

Reiss and Marino (2001) demonstrated the first conclusive evidence for MSR in dolphins. They reported that two captive-born male bottlenose dolphins, ages 13 and 17-years old, exhibited self-directed behavior at a mirror and passed

multiple mark tests. Similar procedures were used as those described in Marino et al. (1994), but this study used the requisite combination of control and test situations. Multiple mark tests were conducted in which the individuals were marked on different areas of their body that could not be viewed in the absence of the mirror. Dolphins were observed in the presence of a mirror in the pre-mark condition for 30 min and then in the post-mark condition for 30 min. The criteria for passing the mark tests required that the dolphin show mark-directed behavior by orienting its body to the mirror such that the mark was exposed to the mirror and that these orientations occurred more frequently in the post-mark versus the pre-mark condition. It was reported that during mirror exposure, the dolphins showed behavioral responses consistent with those reported in chimpanzees. Both dolphins exhibited self-directed behaviors at the mirror (i.e., repetitive body movements, open mouth & close eye viewing, & varieties of bubble production) and in the mark tests, after being marked, the dolphin's first mirror orientations exposed the marked area of their bodies to the mirror. Both dolphins passed multiple mark tests.

Reiss and Marino (2001) reported that their findings provided evidence for cognitive convergence in evolutionarily divergent species, large-brained primates, and dolphins. Bottlenose dolphins, like great apes and humans, have brains that show high degrees of encephalization and neocortical expansion; however, the dolphin brain also differs from those of primates in many ways including aspects of the cortical cytoarchitecture and organization (Marino et al. 2008; Reiss and Marino 2001). Showing MSR in dolphins provides evidence that the ability is not a byproduct of factors specific to humans and their close relatives the great apes but may be linked instead to a high degree of encephalization and cognitive ability more widely distributed than previously thought (Reiss and Marino 2001).

Using similar methodology as Reiss and Marino's (2001) study with dolphins, Morrison and Reiss (2018) conducted a study to investigate the age of emergence of MSR in two young

bottlenose dolphins to identify how humans, great apes, and dolphins compare developmentally with regards to MSR. Young dolphins show precocious sensorimotor and social development, factors that appear to correlate with the emergence of MSR in humans, thus it was predicted that this species might show the early development of MSR. Confirming prior findings of MSR in dolphins, it was reported that one dolphin demonstrated self-directed behavior at 7 months of age, an age earlier than reported for humans, and self-directed behavior was exhibited by both dolphins at a younger age than reported for chimpanzees. Both dolphins passed mark tests at a comparable age reported for children and at a younger age than chimpanzees. The authors suggest that the precocious development of MSR in this species may be attributed to the precocious development of their motor skills, muscle development, coordination, and social awareness at birth, skills that occur later in development in children and great apes.

## MSR in Elephants

Elephants were optimal candidates for MSR studies. They have large brains and relatively high EQ values, are socially complex, and show evidence for empathy (Plotnik et al. 2006) and consolation behavior directed towards conspecifics (Plotnik and de Waal 2014). Povinelli (1989) exposed two adult female Asian elephants to a mirror positioned outside of the bars of the elephants' enclosure and just beyond the reach of the elephants' trunk. Neither elephant exhibited self-directed behavior and both failed to pass the mark test; however, both elephants demonstrated spontaneous mirror-guided behavior to gain access to food that could only be seen in the mirror. Plotnik et al., (2006) tested three adult female Asian elephants that were exposed to a large-sized acrylic mirror affixed to a wall of their outdoor holding yard that the elephants could approach and touch. The elephants followed a similar progression of behavioral stages during mirror exposure as described in chimpanzees (Gallup 1970; Povinelli et al. 1993) and dolphins (Reiss and Marino 2001). All three

elephants exhibited self-directed behavior at the mirror and mark and sham mark tests were simultaneously conducted to control for possible olfactory and tactile cues resulting in only a visual component to differentiate between the mark and sham-mark (see Plotnik et al. 2006). Using the same criterion for passing the mark test as used with chimps, one out of the three elephants tested, passed the test.

Plotnik et al. (2006) suggested that the disparity between their findings and those reported by Povinelli (1989) could be attributed to methodological differences. Povinelli (1989) used a smaller mirror that was placed at an angle outside of the elephant exhibit and the elephants could not touch the mirror. The reflected image of the elephant would have been smaller in comparison to their actual body size. The size and placement of the mirror in the Plotnik et al. (2006) study afforded the elephants the ability and opportunity to see their entire body in the mirror and at its normal size. The mirror was mounted on a wall in the elephants' exhibit allowing the elephants to touch the mirror and determine their proximity to the mirror and the optimal viewing distance. In the majority of studies demonstrating MSR in other species (apes, dolphins, and magpies), the animals had direct access to mirrors as well.

## MSR in Avian Species

Corvids were considered to be good candidates for studying MSR because they exhibit novel foraging behaviors using tools and show evidence of advanced planning and visual perspective-taking (Emery and Clayton 2004; Lefebvre et al. 1997). Magpies and other corvids (e.g., crows, ravens, jackdaws, nutcrackers, & jays) have especially high EQs (Rehkämper et al. 1991) and have developed a relatively large forebrain pallium, although they lack a neocortex. Prior et al. (2008) reported the first evidence of MSR in a non-mammalian species of corvid, the Eurasian magpie. They tested five birds for MSR and three of the five birds showed social behavior that decreased with mirror exposure and instances of contingency-testing

behavior were observed. Sham mark tests (black sticker) and mark tests (colored stickers) were conducted and three of the five birds tested exhibited mirror-mediated mark-directed behavior towards the colored stickers, but not the sham mark (Prior et al. 2008).

Soler et al. (2014) attempted to replicate Prior et al.'s (2008) study by using the same methodology with nine adult jackdaws (*Corvus monedula*). During initial mirror exposure, the jackdaws did not exhibit social behavior; however, they explored the mirror by looking behind it and pecking at it, and they exhibited self-contingent behaviors (Soler et al. 2014). In both the mirror and the control (cardboard, no mirror) conditions, the jackdaws touched and tried to remove the sticker; therefore, it was reported that none of the birds passed the mark test. The authors suggested that using stickers with birds is a methodological flaw because of tactile feedback from the birds' feathers.

More recently, Clary and Kelly (2016) developed what they considered to be an ecologically relevant test of MSR in which Clark's nutcrackers cached alone, in front of a conspecific, in the presence of a blurry mirror, or in the presence of a regular mirror and mark tests (red sticker) were also conducted in each of the mirror conditions. When caching, the nutcrackers did not treat the image in the blurry mirror as a conspecific and they were more likely to investigate the mark in the blurry mirror condition. The authors suggest that these results reveal that nutcrackers may be demonstrating a degree of self-recognition.

Although there are some interesting results with corvids, only the study with magpies (Prior et al. 2008) reported the occurrence of self-directed behavior during mirror exposure prior to being marked, but it was not quantified or described. Further studies with these species should be conducted to determine if they will demonstrate spontaneous mirror mediated self-directed behaviors and to describe such behaviors prior to conducting mark tests with the birds, which has been the standard approach with other species (Gallup and Anderson 2018; Morrison and Reiss 2018).

## Controversy Regarding MSR Research

MSR studies with nonhuman species have stimulated much interest, discussion, and debate regarding the methodology, implications, and significance of these findings (Suddendorf and Butler 2013). Suddendorf and Butler proposed that mark test results have been overinterpreted and the current evidence does not support MSR as indicative of self-awareness, as Gallup and others have proposed. Some discussions have centered on determining what type of data replication and methodologies may be required to provide more conclusive evidence for MSR in other species (Gallup and Anderson 2018). Other discussions have focused on the importance of the emergence and demonstration of self-directed behavior prior to being marked, as well as during mark tests, as requisite evidence for MSR (Morrison and Reiss 2018; Reiss and Morrison 2017) and the use of more nuanced ecologically relevant approaches to investigating MSR (Clary and Kelly 2016).

## Conclusion

MSR in nonhuman species has been a provocative topic in comparative cognition and the wider field of psychology. The discovery of the capacity for MSR in an evolutionarily divergent group of other large-brained highly social species has profound implications regarding the continuity of self-awareness in the biological world. MSR has been correlated with proprioception, social awareness, spatial awareness, EQ level, and with the capacity for empathy (in great apes, dolphins, & elephants), but a comprehensive understanding of all the factors that contribute to MSR remain unclear. The extant studies of MSR in other species have provided insights into the level of self-awareness in some nonhuman minds, although we remain at the periphery of understanding its full dimensions.

## Mitochondrial DNA

Alaknanda Mishra

National Institute of Immunology, New Delhi, India

## Synonyms

Eve gene; mtDNA

## Definition

Mitochondrial DNA is a small circular DNA found in mitochondria.

## Introduction

Mitochondrial DNA (mtDNA), discovered in 1963 by Margit and Sylvan Nass, is a small circular DNA present in the power house (mitochondria) of the eukaryotic cells. It was believed that the mtDNA is only found in the egg and is passed down to both sons and daughters from their mothers until it was found that the copy number of mtDNA is extremely high in oocytes ( $\geq 10^5$ ) as compared to the sperm (50–75), thus explaining the maternal inheritance which could have been a result of dilution of paternal contribution wherein the mitochondria from sperm are lost during embryogenesis. Since mtDNA is a nonrecombinant DNA, it passes down virtually unchanged through the direct maternal line over the generations (Giles et al. 1980; Pakendorf and Stoneking 2005). Therefore, it is also known as the “Eve gene.”

## Need for Mitochondrial DNA

The need for mitochondria to possess its own DNA is still debatable. However, many scientists

proposed “theory of endosymbiosis” which suggested that, billion years ago, mitochondria used to be independent single-celled organisms before they were swallowed by larger cells. Nevertheless, these mitochondria were not digested by these cells and developed a mutually beneficial relationship with the host cells. This mutualism further gave rise to more complex life forms over time (Brown et al. 1979). Another group of scientists also believe that mtDNA is present only to provide local control to mitochondria because pivotal proteins that regulate mitochondrial function are created in mitochondria itself and allow quicker and efficient regulation of energy production by the cell (Picard et al. 2013).

## Structure of mtDNA

Human mtDNA was the first significant portion of the human genome to be sequenced by Sanger’s laboratory, Cambridge, in 1981. There are 16,569 base pairs of mitochondrial DNA in human beings which encode for 37 genes. It also comprises of the control noncoding region (Fig. 1). Thirteen genes coded by mtDNA are essential for

**Mitochondrial DNA, Fig. 1** Representative image of human mitochondrial DNA (Adapted from Pinto et al. 2013)

normal mitochondrial function and involved in making enzymes for oxidative phosphorylation (a process that uses sugar and oxygen to produce ATPs), and the rest of them provide instructions for manufacture of transfer RNA (tRNA) and ribosomal RNA (rRNA) that help in assembly of amino acids into functional proteins. Mutations in mtDNA are generally heteroplasmic, and the wild-type and mutated mtDNA coexist in the same cell. These mutations can be associated to diverse forms of diseases and aging (Pakendorf and Stoneking 2005; Shuwen et al. 2017).

### mtDNA Inheritance

Though mtDNA are inherited through generations from mother to child, it still maintains its variability by the occurrence of high mutation rates due to lack of repair mechanisms and proofreading capabilities. The mutation rates of mitochondrial DNA are ten times higher than in nuclear DNA which may be a result of nucleotide imbalance in mitochondria that causes compromised DNA polymerase gamma fidelity and higher mitochondrial DNA mutation rates (Kujoth et al. 2007). This variability in mtDNA can be utilized in human identity tests, to map out ancestry and migration of a population and to evaluate the evolutionary phylogenetic by analyzing the short variable sections present in the noncoding region of mtDNA. Recently, it has been discovered that mtDNA plays crucial role in innate immune responses and inflammatory pathology and can also act as a novel marker for the prognosis of various diseases including cancer (Lee et al. 2016; Mills et al. 2017; Shuwen et al. 2017; West and Shadel 2017).

### mtDNA Replication

Mechanism of replication in mitochondrial DNA is still being investigated. It was considered for long that the maintenance of mitochondrial genome was simpler than nucleus for many years. Mammalian mitochondria lack all DNA repair systems and possess an eschewed DNA recombination. Mitochondria have only a single DNA polymerase, polymerase- $\gamma$ , and it was

suggested for long that Poly replicates mtDNA exclusively via one mechanism, involving only two priming events and a few proteins which is also referred to as “strand-displacement model.” A mechanism of replication for mammalian mtDNA was elaborated in the early 1970s from EM images of DNA isolated from rodent mitochondria by cesium chloride density centrifugation (Kasamatsu and Vinograd 1973). The EM images of mouse mtDNA suggested a model, whereby leading strand synthesis started at a specific site and advanced approximately two-thirds of the way around the molecule before second-strand DNA synthesis initiated (Kasamatsu and Vinograd 1973). Although it was earlier thought that displaced strand was coated with protein, RNA has more recently been proposed in its place. Furthermore, mtDNA molecules have now been demonstrated to possess all the features of conventional bidirectional replication, suggesting that the process and regulation of replication in mitochondria are complex, as befits a genome that is a core factor in human health and longevity.

### Regulating mtDNA Copy Number

A central question in organelle biogenesis is to determine the mechanism by which the cell controls mtDNA copy number. Based on the mechanism of replication found in mtDNA, it is suggested that the rate of mtDNA replication is determined by a balance between transcription initiation from the lagging strand and subsequent RNA processing steps to provide replication primers. It has not been proved yet that mtDNA copy number is regulated by the levels of mtDNA polymerase or other proteins associated with DNA strand elongation; however, mutations in these proteins may not result in less, or even loss of, mtDNA. It has been suggested that direct activation of the nuclear transcription factor NRF-1 results in stimulation of mitochondrial biogenesis coincident with increased synthesis of mtTFA (mitochondrial transcriptional factor A) owing to the interaction of NRF-1 as an activator of the nuclear gene for mtTFA. This result, along with studies in which loss of mtTFA results in loss of mtDNA and mitochondrial function, raises the

probability that mtTFA is a central feature of not only mtDNA transcription and replication but of organelle biogenesis itself (Holt et al. 1988).

## Conclusion

Human mitochondrial DNA (mtDNA) typically forms 5- $\mu$ m circles, or 16.5 kilobases, one genome in length. The mtDNA varies largely in size and form outside animal kingdom, yet it exists without fail to provide the cell with essential components of the respiratory chain (and ATP synthase). Therefore, any mutation caused in mtDNA can lead to respiratory chain dysfunction, which results in rare diseases in plants (Levings and Pring 1976; Newton and Coe 1986) and humans (Holt et al. 1988). Since budding yeast can grow anaerobically, hence, it can survive without mtDNA (Goldring et al. 1970). Also, the vertebrate cells cultivated in the laboratory on a diet of glucose far less concentrated than soda can achieve the same feat (Desjardins et al. 1985). Nevertheless, it is impossible for even a simple free-living multicellular organism, such as the nematode worm, to survive without mtDNA (Brown et al. 1979; Pakendorf and Stoneking 2005).

## Mitosis

Sangita Santra  
The University of Burdwan,  
Burdwan, West Bengal, India

## Synonyms

Cell division; Equational division; Somatic cell division

## Definition

Mitosis is the process where a parent cell divides into two daughter cells and each receives an exact copy and number of the chromosomes (genetic material) and is called as equational division. It maintains cell growth and repair.

## History

In the seventeenth century, cellula was discovered as a building block of many organisms by Hooke, Van Leeuwenhoek, and others (Hook 1665; Leeuwenhock 1662). In the first half of the nineteenth century, Schleiden and Schwann established the cell theory, according to which all organisms are composed of tiny units, the cells (Schleiden 1838; Schwan 1839). In 1875, Strasburger published a comprehensive book about cell formation and cell division (Strasburger 1875). Strasburger's colleague Walther Flemming started detailed studies on dividing cells in different organs and organisms, mainly from animal kingdom. In 1873, Schneider drew the different steps of cell division (Schneider 1873). In between 1874 and 1876, Flemming described in more details whereas Schneider had postulated that the nucleus undergoes deformation during cell multiplication (Flemming 1874, 1875, 1876). Flemming showed that the scaffold and network within the nucleus transformed into "threads" which then separated into two groups. These two groups in turn formed two skeins, from

which the scaffold of the nuclei reappeared. By carefully studying wounds and scars, Flemming and his students found an accumulation of dividing cells in these tissues and concluded that the regeneration of tissues and organs occurs by cell division. In 1878 and 1879, Flemming coined the term "indirect nuclear division" because he had observed that a transformation of nuclear content had to take place before fission could occur. A cleavage of the nucleus and protoplasm which until then had been generally assumed was called direct nuclear division (Flemming 1878, 1879). The methods that Flemming had developed allowed to recognize a fibrous scaffold in nucleus which could easily be stained and was therefore named chromatin (stainable materials). In 1882 Walther Flemming introduced the term (derived from the Greek word, meaning thread).

## Stages of Mitosis

One round of DNA replication is followed by single round of chromosomes segregation to generate two genetically identical daughter cells.

Mitosis starts with the nuclear division (karyokinesis), corresponding to the formation of daughter nuclei, and usually ends with division of cytoplasm (cytokinesis). Mitosis is continuously divided into four stages: prophase, metaphase, anaphase, and telophase.

### Karyokinesis

#### Prophase

The first stage of mitotic cell division is prophase. At prophase the replicated chromosome with two closely related sister chromatids starts condensing. The mitotic spindle assembles outside the nucleus, between the two replicated and moved apart centrosomes (Fig. 1).

### Events Involved in Prophase Stage

1. The chromatin, which is visible in interphase, slowly condenses into well-defined chromosomes.
2. Each chromosome has duplicated during preceding S phase, and each of these sister

chromatids is held together at a centromeric region (constricted region).

3. At centromere, the sister chromatids are kept together by a member of the SMC (structural maintenance of chromosomes) family of proteins called cohesin. Cohesin is a protein complex composed of four subunits (Smc1 and Smc3 with two ATPase domains and two additional subunits Scc1 and Scc3, with ATPase domains forming a ring structure).
4. Prophase ends with the disappearance of nucleolus and breakdown of nuclear envelope. Nuclear envelope disruption is a complex multistep process that begins when M-CDK phosphorylates several subunits of the nuclear pore complexes present in the nuclear envelope, and this initiates the disassembly of nuclear pore complexes.
5. M-CDK phosphorylates components of the nuclear lamina which lies beneath the envelope. The phosphorylation of nuclear lamina components results in disassembly of the nuclear lamina and breakdown of membrane envelope into small vesicles.
6. In most cells, the disruption of the nuclear envelope marks the end of the prophase of mitosis. However, this disruption of the nuclear envelope is not a universal feature of mitosis and not found in all cells.
7. In some lower eukaryotes (e.g., yeasts), the nuclear envelope remains intact and chromosomes migrate to opposite poles within the nucleus. This is termed as closed mitosis. The cells of higher eukaryotes undergo the breakdown of the nuclear envelope at the end of the prophase which is known as open mitosis.
8. At the end of the prophase, the cytoplasmic microtubules are disassembled, and the mitotic spindle begins to form. Mitotic spindle is a bipolar structure composed of microtubules and associated proteins.
9. The spindles assemble outside the nucleus between separating centrosomes.
10. The nuclear division in mitosis is mediated by a microtubule-based mitotic spindle which separates the chromosomes. Spindles are also called microtubules each of which made up of polarized tubulin polymer from one

end, the minus end, embedded in a spindle pole and the other end, the plus end, pointing outward from the pole. The mitotic spindle is of three types: kinetochore microtubules, polar microtubules, and astral microtubules.

### Metaphase

The chromosomes are aligned at the equator of the spindle or midway of the spindle poles in metaphase. The kinetochore microtubules attach sister chromatids to opposite pole of the spindle (Fig. 1).

### Events Involved in Metaphase

1. Metaphase is an extremely dynamic part of the cell cycle. The completion of spindle assembly in animal cells requires nuclear envelope breakdown, and prometaphase starts abruptly with breakdown of the nuclear envelope.
2. The event of assembly and disassembly of spindle fibers occurred once they originate from MTOC to reach the required length.
3. Spindle fibers attach to a specialized structure, the kinetochore, at the site of chromosome. Kinetochores are of two types facing in opposite directions on each chromosome.
4. Chromosomes make attachment with the spindle fibers by the process known as "search and capture" in which the plus ends of some microtubules radiating out from the MTOC attach to kinetochore. Some microtubules randomly hit kinetochore and subsequently stabilized to form kinetochore microtubules. Eventually the opposite kinetochore on the other sister chromatid is captured by the free end of a microtubule from the opposite pole. This leads to bipolar orientation of chromosome.
5. The movement of chromosomes during metaphase depends on numerous microtubule-dependent motor proteins. These proteins belong to two families – the kinesin-related proteins (such as kinesin-5, kinesin-14, kinesin-4, and kinesin-10) and dynein.
6. Kinesin-5 protein (plus end-directed motor protein) interacts with the plus ends of anti-parallel polar microtubules in the spindle midzone and pushes the poles apart.

**Mitosis, Fig. 1** Linear diagram showing the different stages of mitosis starting from parent cell in interphase to early prophase, late prophase, metaphase, anaphase, and telophase which produces two daughter cells after cytokinesis

- Kinesin-14 proteins are minus end-directed protein (toward pole from kinetochore). The heavy chain of kinesin consists of motor domain (head), the helical coiled coil domain (neck), and the carboxy-terminal tail domain attached to light chain. Once ATP hydrolysis occurs in the motor domain (ATP-dependent microtubule-binding domain), it helps in changing the conformation and orientation of the neck with reference to head results in the motion. Kinesin-14 family member motors can bind to, crosslink and slide of microtubules which helps in spindle assembly and to pull together (She and Yang 2017).
- Kinesin-4 and kinesin-10 proteins (also called chromokinesin) are plus end-directed motors that associate with chromosome arms and push the attached chromosome away from the pole.
  - Finally, the minus end-directed dynein motors link the plus ends of the astral microtubule to the cytoskeleton component of the cell cortex. The dynein motors pull the spindle poles toward the cell cortex.
  - At metaphase stage, chromosomes aligned at the midpoint between the two spindle poles. During this process chromosomes often oscillate backward and forward before arriving at the midpoint. Multiple forces move chromosome at the equator. One major force pulls the chromosome along the kinetochore microtubule toward the spindle pole. It is produced by proteins at the kinetochore itself.
  - Depolymerization at the plus end of the microtubule somehow generates such force that pulls the kinetochore poleward. Kinetochore-localized kinesin-13 (a class of microtubule-depolymerizing protein) and CENP-E (a member of kinesin-7) play an important role.
  - Apart from poleward forces, each chromosome is simultaneously subjected to

anti-poleward forces. The force acting on chromosomes is the polar ejection force. Plus end-directed motor proteins kinesin-4 and kinesin-10 located on the chromosome arms interact with polar and astral microtubules to produce the anti-poleward polar ejection forces. This force pushes the chromosomes toward the equator. The combination of these forces makes the chromosome alignment on the metaphase plate. The alignment of chromosomes at the metaphase plate, midpoint between the two spindle poles, is called congression.

### Anaphase

This is the third phase of mitotic cell division in which chromosomes move away from one another to the opposite of the spindle poles (Fig. 1).

#### Events Involved in Anaphase

1. At metaphase two sister chromatids attach to the kinetochore microtubules which pull two kinetochores toward the opposite pole.
2. Sister chromatids are tightly attached together at their centromere by multiple protein complex which is called cohesin.
3. During anaphase separase degrades cohesin molecules in between two sister chromatids.
4. Before anaphase a securin protein binds with separase protein and keeps it in inactive state.
5. After degradation of securin, it releases separase which is then free to cleave cohesin complex.
6. M-cdk activates APC complex and then initiates ubiquitination and degradation of securin.
7. Each chromatid is pulled slowly toward the poles by two independent and overlapping process. The separated chromatids are now called chromosomes.
8. Anaphase can be divided into two processes: anaphase A and anaphase B.
9. In anaphase A, the initial poleward movement of chromosome and shortening of kinetochore microtubules occur. In this phase the force is generated by microtubule depolymerization at the kinetochore which results in the loss of tubulin subunits at the plus end as the kinetochore moves toward the pole. Kinesin-7 and kinesin-13 that are located at the kinetochore help in the movement toward the spindle poles.
10. Three basic processes help in the separation of the poles in anaphase-B (Lodish 2013).
  - (a) Pushing force – kinesin-mediated sliding of polar microtubule past one another.
  - (b) Pulling force – cortex-associated cytosolic dynein.
  - (c) At the minus end, polar microtubules lengthen.
11. Kinetochore dynein helps in segregation of chromosome acutely by delaying anaphase to properly attach the chromosome to the spindle (Foley and Kapoor 2012).

### Telophase

1. In telophase the separated daughter chromosomes are located at the poles, and the kinetochore microtubules disappear.
2. The polar microtubules elongate even further, and a new nuclear envelope re-forms around each group of daughter chromosomes.
3. The condensed chromatin expands and the disappeared nucleolus starts reappearing again at the end of mitosis (Fig. 1).

### Cytokinesis

1. Cytoplasm of the cell is divided by cytokinesis; it begins in anaphase and ends in telophase reaching completion as the next interphase begins.
2. During cytokinesis, the cytoplasm is divided by a process called cleavage.
3. Cleavage is accomplished by contraction of circumferentially oriented contractile ring which is made up of actin filament and myosin II.
4. This contractile ring which is known as cleavage furrow generates force required for cleavage.
5. The function of the contractile ring at the site of cleavage is controlled by RhoA (a small GTPase of the ras superfamily).
6. The myosin II assembly and contraction require other protein kinases, including Rho-activated kinase ROCK.

7. This kinase phosphorylates the regulatory subunit of myosin light chain and promotes the assembly and contraction of the actin myosin ring.
5. Apical and lateral cambium growth occurs through mitosis in meristematic tissue in plant throughout the life.
6. It maintains cytoplasmic growth in the cells.

## Mitosis-Related Abnormalities

In mitosis, cells can divide, and it creates two identical daughter cells that carry an original copy of parental DNA, and error of this process results in incorrect DNA copies. These errors result in the health of organisms.

| Diseases      | Causes                                                                                                                                                                                                                                                                                                                                                               |
|---------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Cancer        | Two types of errors occurred during DNA replication in the form of missense or silent mutation which can multiplies over times and go through cell cycles and lead to tumors. Cancer occurs when mutated cells are ignored by checkpoint and begin to reproduce uncontrollably                                                                                       |
| Down syndrome | Due to failure of chromosomal attachment to the spindle, the poleward movements of chromosome get hampered. Consequently, non-disjunction produces cells with abnormal copies of chromosome as aneuploidy. Down syndrome occurs due to such abnormalities in chromosomes 14 and 21 (trisomy 21)                                                                      |
| Alzheimer     | Trisomy 21 exhibits Alzheimer neuropathology by the time they are 30–40 years old because the gene for APP (amyloid precursor protein) resides on chromosome 21 and its consequent overexpression in trisomy 21 cells presumably contributes to the development of Alzheimer's disease in Down syndrome. Mis-segregation of chromosome in mitosis is the reason here |

## Significance of Mitosis

1. This biological process helps in growth and development of multicellular organism.
2. It helps in maintaining the proper size of somatic cells.
3. It helps in repairing of damaged tissues.
4. It is responsible for maintaining the same number of chromosomes in daughter cells after division.

## Conclusion

Mitosis is the process of duplication of cells with equal number of chromosomes in daughter cells as compared to parent cells. It helps in normal growth and development of individuals and repairing of tissue. The abnormalities in the division cause different disease pathologies in the individual.

## Definition

Mathematical model fitting of animal behavior and cognition constitutes mathematical expressions which accommodate key variables involved in particular behavior under the certain condition of environment or stimuli presented.

## Introduction

Animal behavior involves a complex mixture of sensory, biomechanical, and neuronal restrains. Because of the complexity of behavior schema, it is impossible to account for all the factors which have their role in the particular behavior. So, the mathematical models are the tools which regress out the certain variables associated with the behavior, and thus mathematical abstractions based on that present the key to assessing quantitative prediction about behavior in certain conditions. Though these models do not present the full array of factors, the model itself if fitted well to behavior can predict the behavior with precision and accuracy resulting to less ambiguity of modeling and easier testing in silico.

Organized movement displayed by an organism is termed as behavior. Some behaviors are individualistic in nature, while some behaviors are of the collective type. Behavioral organization involves:

- (a) Sensors (receptors) which act as an input for the internal milieu

- (b) Channels for information flow, i.e., neuronal pathways, conducting information, etc.
- (c) Effectors

And to predict the outcomes, model fitting is done for the behaviors which help to assess the cognitive parameters behind it. Mathematical modeling is an investigative technique which uses a mathematical expression of a system accounting, may be all or some of its known properties. Modeling for researchers is the powerful tool of scientific analysis. The simpler the model accounting for variables essential for the behavior, the better it is. Also, it is important to distinguish the rational mathematical models based on hypotheses from the empirical mathematical models, as empirical models do not support knowledge acquired based on scientific theories. Rational theories are derived from a number of basic theories and provide good fitting with the observed experimental data. If the model fitting fails for particular behavior, then it proves that the tested theory cannot be applied to the data set available.

**Model fitting of animal behavior can be based on one of the given based strategies/models:**

- A. **Deterministic:** In deterministic modeling observations can be defined by a limited well-defined set of an outcome, and the prior outcomes of some experiments can be represented by their representative different outcomes.
- B. **Stochastic:** In stochastic modeling the probabilities are assigned to each of the event in a paradigm. If the probabilities observed are close to unity, then the model can be termed deterministic.
- C. **Statistical Models**

## Mathematical Models of Behavior

- (a) **Teleological determinism:** In teleological determinism the subject chooses behavior based on the assumption that this behavioral outcome will be beneficial.

Two groups of theories to define it: (i) game theories, based on Nash equilibria principle, and (ii) reinforcement theories, based on Skinnerian reinforcement principle or matching law (Coley and Tanner 2015).

Here the parameters used are dimensionless or represented by per second.

- (b) **Causal determinism:** In causal determinism subjects do not choose from the set of possibilities/available opportunities, but rather they are prompted to do what is prefixed in hypothesis, doing so in response to a specific stimulus. Here, behavior occurrence is the result of sufficiently strong stimuli being presented.

Here the parameters are in SI metrics system.

## Game Theory

Game theory is special for researchers when they have to model the influence of evolution over strategies and tactics, since choosing the right strategies (natural selection helping winners to combat in adverse situations) is the key point deciding success in life. The theory of human games applies to animal behavior; it gives a scaffold over which behavioral choices made by animals can be analyzed.

**Nash equilibrium (NE):** John Nash proposed an optimal model for collective strategy involving two or more players; he has defined the terms where if each player in the game has strategy fixed and none of the player is benefitted by changing the strategy while the other players choose to stay with their fixed choices, the set of strategy choices and corresponding leads in game constitutes Nash equilibrium (NE).

In Nash's game it can have a pure strategy NE or the mixed extension in NE, where pure strategy is chosen stochastically. In the latter, mixed strategies (players choosing strategies in random according to preassigned probabilities), for every n-player game, every player can make a choice from the finite number of strategies leading to at least one Nash equilibrium.

**Evolutionary stable strategy (EES):** Strategies by animals which cannot be perturbed by the other strategies. Concept of an EES is the crucial

and important part dealing with game theory. EES is able to withstand the budding new strategies over evolution. So, here the natural selection will provide for the base over which different strategies can be tested, and computational biologists simulate the behaviors in the best possible fitting manner (Brown 2016).

Applying game theory for analysis of an animal behavior is the most plausible approach for mathematical modeling. Though teleological determinism is the best suited to explain the outcomes, same time they are quite useful.

### Matching Law

Matching law states that the choice made is neither solely an internal decision nor an isolated output of an internal decision processes; here the choices are rated based on overt events strung over time. So according to matching law, the model will predict alternative activities PL or PR, and allocation of their behavior to activities in proportions corresponding to the relative rates of reinforcement, RL and RR, e.g., time spent by animal in mating, eating, etc. (Kubaneck and Snyder 2015):

$$PL/(PL + PR) = RL / (RL + RR)$$

### Modeling Individual Animal Behavior

Individual behavioral mechanisms are defined by their respective individual's probabilities to display the behavioral outcome, whether it is some action or change in the state (Buhl et al. 2005).

**Optimality models:** These models quantitatively predict the consequences faced by an animal when presented to the conditioned environment. According to this model strategy, the animal will behave to maximize their fitness. Optimality model evaluates fitness benefits (B) and the fitness costs (C) for the different values presented on the decision scale. Optimality model using calculus and logical tool helps to evaluate minima and maxima of a particular function  $f(x)$  by assessing its derivatives  $df(x)/dt$ . The model aims to optimize "decision variable." "Constraints" are barriers in the relationship between decision variable and "currency: to

check the outcome of decision variables." This approach is key to access sensitivity to changes of decision variables determining what type of information are valuable for the currency-decision variable relationship.

#### 1. Optimal Foraging Theory: Model examining choice of food items

Selection of food item is a behavior which every animal shows, and this is based on the basic instinct of an organism to maximize its currency; currency here is a number of calories present in particular food item. E1 and E2 refer to the caloric energy contained in two different food items/prey. H1 and H2 are the handling time needed to access the caloric content of food. So, the model prefers food/prey for which estimates of energy gained per unit of time are higher,  $E1/h1 > E2/h2$ . This model defines the behavior of the predator either as a specialist or the generalist (Sayers and Menzel et al. 2012).

#### 2. Marginal Value Theorem (MVT)

MVT is an optimality model that usually describes the behavior of an optimally foraging individual in a system where resources (often food) are located in discrete patches separated by areas with no resources.

This model attempts to optimize a cost/benefit ratio; it is an optimality model describing the behavior of an individual in a system where the resources are dispersed in discrete patches with the areas of void, i.e., without resources (Calcagno et al. 2014).

### Modeling Collective Animal Behavior

Diversity and complexity observed in the behavioral patterns of swarms, flocks, and crowds are the examples of collective behavior shown by the population; they may be the result of relatively simple interactions happening between the individuals. Collective behavior is displayed as dynamical patterns grouped by the self-organizing processes involving simple individual behaviors. Temporal and spatial characteristic lengths of dynamical patterns formed during collective animal behavior are much larger than the typical ranges observed under individual interactions.

Modeling of collective animal behavior will lead us to causally link these studies with the studies dealing with neural and cognition basis of individual behavior and collective behavior in which these neuronal and cognitive processes are involved (Weitz et al. 2012).

For evaluation of cognitive capabilities based on modeling of collective animal behavior, the key basis is to sort out all possible biological parameters involved in determining individual behaviors and then deduce the relative collective outcome. And it provides for the simplest way where self-organization of an individual behavior is seemed as the components of an observed collective behavior.

### Collective Behavior of Corpse Clustering in Ants

Ants *Messor sancta* show behavior, clustering broods, leaf fragments, sand pellets, and corpses of their dead conspecifics. While looking for their collective behavior ant movement, picking of corpse and dropping it in pile of high density or low density are seen as one action (Jost et al. 2007).

For exemplifying and for better resolution, the three different protocols based on segregation of an action involved in performing a collective behavior task is used for:

- (a) Movement of ants
- (b) Picking up
- (c) Deposition

Three model ingredients and their corresponding cognitive significance in corpse clustering tasks can be parameterized based on:

- 1. Influence of the perceived object density
- 2. Importance of interindividual variability
- 3. Role of individual temporal correlation

How the interactions between individuals work in order to control the collective behavior is still not resolved. Individual behavioral mechanisms refer to the individuals' probabilities to perform an action, determining the causal link between neural and cognitive processes with the

individual behaviors helping to further resolve enigma of collective behavior.

### Modeling and Its Rationale, Difficulties, and Possible Solutions

A very demanding task is to have a clear demarcation separating different behavioral models based on the defined combination of biological concepts and their formal translation into mathematical representations.

Mathematical expressions depend on the limited set of quantitative variables involved in fitting the functional dependencies for the behavioral outcomes seen under a task/stimuli presentation, and complete model translation requires arbitrary choices to be made for the state variables and stimuli that can be deduced as direct consequence of the model.

Understanding of mathematical modeling in biology fluctuates:

1. One according to which the equation is the essence, pure ideal design of a complex biological process
2. Second, that a simple equation is a crude approximation, a formal representation of a hypothesis which is only valid if its assumptions agree with empirical data obtained under certain conditions

Equations though inherent are perturbed by many factors in nature. Theory of deterministic chaos, dealing with nonlinear parameters, things effectively impossible to predict/control, capturing infinite complexity of nature. Fluctuating power spectrum with exponential frequency dependency of behavior will help to model nonlinear parameters.

In movement ecology linking animal movement patterns, chaotic dynamics are linked to underlying biological processes, including those operating at neurobiological level. Hallmarks of chaotic dynamics are seen in movement patterns of mud snails (*Hydrobia ulvae*), moving in controlled conditions, observed in temporal dynamics of turning behavior.

Levy walks (LW) are made by mud snails with their mechanistic origin in chaotic neuronal processes, opening window for new research over coupling between neurobiology and motor properties helping to distinguish intrinsic movement behavior of animals from observed movement patterns, affected by various environmental factors. Levy search, a complex scale-free behavior – alternate clusters of many short steps with longer steps between them – creates fractal movement patterns having no characteristic scale (Andy Reynolds 2015). LW is important for random searches. Hayashi et al. provided the first evidence of neurons having chaotic dynamics. Findings by the researcher have focused on chaotic dynamics, and with the results we know, spontaneous flight patterns seen in *Drosophila melanogaster* are linked to spontaneous neuronal firing in central complex (Chang et al. 2017). **Pacemaker neurons** in molluscs observed to show chaotic temporal dynamics linked to the chaotic behavior in movement pattern seen in molluscs.

## Flaws in Study of Animal Behavior and Thus the Models Proposed

Uncritical adaptationist thinking is the major flaw (Gould and Lewontin 1979); the appropriate approach is to formulate optimal hypotheses for the particular function of the complex behavior; once it is selected, the controlled assessment of hypotheses is a must.

## Synonyms

Modern synthetic theory

## Definition

The modern synthetic theory of evolution describes the evolution in terms of genetic variations in a population that leads to the formation of a new species.

## Introduction

Darwin's book, *The Origin of Species by Means of Natural Selection*, founded a strong ground for evolutionary theories that favored the idea that all the organisms have descended from a common ancestor. Darwin proposed natural selection as a mechanism of evolution. Then came the neo-Darwinian theory of evolution that explained the significance of mutations and variations within a population, as a driver factor of evolution. This perspective was followed for many decades.

Ronald Fisher and his colleagues set Darwin's concept of natural selection on a new foundation of genetics. They left an equally major project open for later biologists: to explain in the language of genes what species are and how they originate. While the Darwin's theory largely demonstrated the "facts" of evolution, the

"mechanism" of evolution was still unexplained. The answer only began to emerge in the 1930s, thanks in large part to the work of a Soviet-born geneticist named Theodosius Dobzhansky, who proposed the idea of modern synthesis.

However, a quiet majority of geneticists thought of species' origin as the gradual accumulation of small mutations, and in 1940 this allowed for propagation of "the synthetic theory of evolution" by geneticist Theodosius Dobzhansky (1900–1975) and other zoologists.

The neo-Darwinian view was then replaced by a new concept which considered several other mechanisms in addition to natural selection. These ideas on evolution are usually referred to as the modern synthesis which is described by Futuyma as "The major tenets of the evolutionary synthesis, then, were that populations contain genetic variation that arises by random (i.e. not adaptively directed) mutation and recombination; that populations evolve by changes in gene frequency brought about by random genetic drift, gene flow, and especially natural selection; that most adaptive genetic variants have individually slight phenotypic effects so that phenotypic changes are gradual (although some alleles with discrete effects may be advantageous, as in certain color polymorphisms); that diversification comes about by speciation, which normally entails the gradual evolution of reproductive isolation among populations; and that these processes, continued for sufficiently long, give rise to changes of such great magnitude as to warrant the designation of higher taxonomic levels (genera, families, and so forth)" (Futuyma 1986).

## Modern Synthetic Theory of Evolution

The modern synthetic theory of evolution describes the evolution in terms of genetic variations in a population that leads to the formation of a new species. It explains the contribution of factors such as genetic variations, reproductive and geographical isolation, and natural selection. It also describes about the Mendelian population, gene pool, and gene frequency. It merges the concepts of Darwinian theory of evolution and

Mendelian genetics to form a unified theory of evolution. Synthetic theory of evolution was introduced by few renowned evolutionary biologists naming T. Dobzhansky, J.B.S. Haldane, R.A. Fisher, Sewall Wright, G.L. Stebbins, and Ernst Mayr in the years 1930–1940.

The modern synthetic theory of evolution proposed a new definition to the evolution as “the changes occurring in the allele frequencies within the populations,” which accentuates on the genetics of evolution.

### Aspects of Modern Synthetic Theory of Evolution

Some of the factors describing the modern theory of synthetic evolution can be explained as follows.

#### Recombination or Variation

Recombination occurs between the existing genes to form a new genotype. It is an exchange of the chromosomal pairs of alleles during the meiosis at the time of sexual reproduction to form new gene combinations. Cytogenetic events such as mutations (including deletion, inversion, duplication, translocation, and polyploidy) result in the recombination.

#### Mutation

A mutation is a change in DNA, the hereditary material of life. An organism’s DNA affects its phenotype, its behavior, and its physiology. Mutations are the raw materials of evolution. Evolution is categorically dependent on mutations because it enables the formation of new alleles and new regulatory regions.

#### Heredity

The transmission of variations from the parents to their offsprings is a principal mechanism in the evolution. The organisms which retain hereditary characteristics are preferred in the struggle for the existence.

#### Natural Selection

Natural selection is a phenomenon by which species adapt to their environment. Natural selection results in an evolutionary change when

individuals with certain characteristics have a greater survival or reproductive rate than other individuals in a population and pass on these inheritable genetic characteristics to their offspring.

#### Reproductive Isolation

It is one of the crucial factors responsible for the synthetic theory of evolution. Reproductive isolation helps in preventing the interbreeding of related organisms. Additionally, some other factors that contribute to the synthetic theory of evolution include migration of individuals from one form of the population to another and hybridization between the races of species which increases the genetic variability within the population.

It differs from Darwinism in three important aspects:

1. In addition to natural selection, it considers several mechanisms such as random genetic drift to be an important element of evolution.
2. It describes that the characters are inherited as discrete units called genes. Occurrence of multiple alleles of a gene within a population gives rise to variation.
3. It postulates that speciation is (usually) due to the gradual accumulation of small genetic changes. This is equivalent to saying that macroevolution is simply a lot of microevolution.

Modern synthesis was one of the utmost accomplishments of evolutionary biology. By combining the concepts of Darwin and Mendel, it expounded that diversity within a population ascended from random occurrence of mutations and environment acted to select the phenotype that is more fit. Potential reproducing animals transmitted the genes that were advantageous. These types of genes included those coding for enzymes with better rates of synthesis and globins with better oxygen-carrying capacity. It was presumed that the genetic variations, that caused evolution within a species, also caused evolution of a new species. If a new phenotype is to be produced, it is essential that there should be an accumulation of these mutations followed by reproductive isolation. The theory of modern synthesis not only did explain the evolution within

species but also explained many relevant questions such as why some alleles that seem to be deleterious get selected in certain populations, for example, one of the hemoglobin gene variants results in sickle cell anemia. The population genetic approach to evolution was summed up by Theodosius Dobzhansky, who stated that “Evolution is a change in the genetic composition of populations. The study of the mechanisms of evolution falls within the province of population genetics” (Dobzhansky 1951).

Thus, some of the core assumptions of modern synthesis include five major postulations which include:

1. Phenotypic variations of evolutionary significance arise from genetic mutations occurring at a low rate and independent of the strength and direction of natural selection.
2. Most of the advantageous mutations show small phenotypic effects which progressively lead to the change in phenotype.
3. Inheritance is genetic in nature.
4. Natural selection is an exclusive explanation for adaptation.
5. Accumulation of variations that arise through microevolutionary processes results in macroevolution.

### Significance of Developmental Biology in Modern Synthesis

At the time when the concept of modern synthesis was formulated, developmental biology and developmental genetics was at a naive stage. Significance of embryology was neglected and was kept out of modern synthesis by most of the geneticists and evolutionary biologists (Hamburger 1980; Gottlieb 1992; Dietrich 1995; Gilbert et al. 1996). It was earlier assumed that population genetics is enough to explain the evolution; hence, developmental biology seemed to contribute almost negligible in the modern evolutionary theory (Adams 1991). However, it is not well accepted that “developmental genetics approach to evolution concerns more the *arrival* of the fittest than the *survival* of the fittest” (Gilbert 2000). Even the critics of modern synthetic theory agreed that macroevolution, which refers to the large morphological changes that are

seen between species, classes, and phyla, is based on mutation and recombination. Nevertheless, these macroevolutionary variations occur in developmental regulatory genes in the embryo and larvae, and not in adults competing for reproductive success (Waddington 1953; Gilbert 1998).

Developmental biology has brought a new platform to understand the relationship between genotype and phenotype in the light of evolutionary biology. Also, it enables us to understand the genetic relationships between diverse organisms. Developmental biology thus provides a population genetic approach to understand gene regulation (Arthur 2000; Macdonald and Goldstein 1999; Zeng et al. 1999). It opens questions as to how various paracrine factors, transcription factors, and signal transduction pathways were modified during the evolution.

Evolutionary developmental biology also provides answers to many classical evolutionary questions such as those of the examples of mimicry and industrial melanism. Now that the genes responsible for such phenomena have been identified, the mechanism can be very well explained (Koch et al. 1998; Brakefield 1998). Thus, to explain the mechanism of evolution, both the population and developmental genetics should be taken under consideration.

### The Extended Synthesis

The concept of modern synthesis emerged in first half of the twentieth century and flourished for many years. However, as the evolutionary biology research progresses, several research subjects emerged that transcended the boundaries of modern synthesis. Major thrust areas that challenged the theories and concepts of modern synthesis included epigenetics, phenotypic plasticity, evolutionary developmental biology, and systems biology. This new conceptual framework of evolution was termed as extended synthesis, as it was an extension, rather than contradiction, to the modern synthesis (Pigliucci 2007). An excellent description of this is provided in the book “*Evolution—The Extended Synthesis*” (Pigliucci and Müller 2010).

Epigenetics has been one of the major thrust areas in extended synthesis. The term “epigenetics” was first introduced by Conrad Waddington in the

early 1940s (Waddington 2011). He defined epigenetics as “the branch of biology which studies the causal interactions between genes and their products which bring the phenotype into being”. However, as the field of genetics expanded, it is now defined as, “the study of changes in gene function that are mitotically and/or meiotically heritable and that do not entail a change in DNA sequence” (Morris 2001). Epigenetic mechanisms include interactions among various genetic, physiological, and morphological systems and serve as an important constituent of organism-environment interactions (Angers et al. 2010; Richards et al. 2010; Schrey et al. 2012).

The significance of epigenetics at molecular level has been well elucidated and appreciated for, e.g., its function in cell determination and cell recognition; however the role of epigenetics in evolution is recently under attention. Some epigenetic characters are known to stably transmit across generations, which highlights that it includes some mechanisms of heredity which was not considered in the framework of modern synthesis.

Epigenetic mechanisms play critical roles and several mechanisms such as in phenotypic plasticity, invasive species biology, soft inheritance, response to environmental variations, and conservation biology. Epigenetic variations such as DNA methylation provide an evolutionarily significant source of phenotypic variation among individuals. DNA methylation is the most studied molecular epigenetic mechanism. It is actively involved in mechanisms such as DNA imprinting, X-chromosome inactivation, silencing transposable elements, and response to environmental stressors. DNA methylation is a basis for interindividual variation and is studied to regulate various phenomena such as phenotypic variation in shape of flower and fruit pigmentation, shape of mouse tail, body size and coat color, and numerous traits differentiating queen and worker honeybees. For example, *Viola cazorlensis* shows a high level of interindividual DNA methylation variation that differentiated populations (Schrey et al. 2012).

Nevertheless, DNA methylation serves as the most comprehensively studied mechanism in ecology and evolutionary perspectives; several

studies have described other epigenetic mechanisms also. Modifications of histone, small and long noncoding RNAs, and genome structure are shown to regulate gene expression and contribute to phenotypic variation in diverse taxa.

Epigenetics continues to prove as a remarkable phenomenon in evolutionary biology. A great deal of work, however, remains to be done. Pragmatic studies that established the significance of epigenetic variation in evolution will likely explain some of the empirical questions of evolutionary epigenetics, which will further help in development and enhancement of a foundational theory of evolutionary epigenetics. Thus, epigenetics studies seem to be very promising in providing information about the individual and population processes both at the ecological and evolutionary timescales.

## Synonyms

[Mollusca](#)

## Definition

Mollusks are the members of a diverse group of invertebrates with a thin fleshy soft unsegmented body, divisible into a head, visceral mass, and foot. Members of this phylum exhibit an “organ system” grade of the organization (Anderson 2001), e.g., snails, octopus, squids, oysters, chitons, mussels, etc.

## Etymology

The term mollusk was coined by the French naturalist Lamarck. This term is originated from the Latin word *molluscu*, meaning “thin shelled,” derived from the root Latin word *Mollis*, meaning “soft.” Cuvier first used the term in 1798 to describe the animals with reduced shells, such as cuttlefish, snails, squids, etc. The study of mollusks is known as malacology, whereas mollusks’ shell study is called conchology. Due to the vast diversity of species and many fossil forms, they are considered the largest marine phylum and comprise about 23% of all marine organisms (Amsler et al. 2001). They constituted the second-largest phylum of non-chordate after arthropods and were believed to appear during the Cambrian period (Ruppert and Barnes 1994).

## Present Taxonomical Status

The phylum Mollusca is considered one of the most conspicuous of the invertebrate group, consisting of about 220,000 living species. The fossil record also indicates a long and extensive history (Telford and Budd 2011). Mollusks are one of the largest metazoan phyla, which includes about 130,000 described extant species and about 70,000 described fossil species (Haszprunar et al. 2008). As per Ponder and Lindberg (2008), Mollusk fauna’s total living species diversity comprises 20,000–30,000. According to modern taxonomists, the following classes include the mollusk phylum: the Gastropoda (slugs, snails, etc.), the Bivalvia or pelecypods (mussels,

clams, etc.), the Cephalopoda (sepia, cuttlefish, octopus, etc.), the Polyplacophora (chitons), the Scaphopoda (dentalium), the Monoplacophora (univalves), and the Aplacophora (Barth and Broshears 1982).

## Habit, Habitat, and Ecological Importance

Mollusks’ habitat ranges from the deepest ocean to intertidal/abyssal zone, freshwater, and lands. A few members form a significant part of freshwater fauna, and the others include terrestrial habitat. They are found on rocky, sandy, or muddy substrata, and some members are burrowing, some are crawling, few members become attached to a substratum, or some are free-swimming forms. Among all classes, Gastropoda is the most important and comprises more than 80% of all mollusk species (Fortunato 2015). Cephalopods such as squids, cuttlefish, etc. are considered the most neurologically advanced invertebrates (Amsler et al. 2001).

Mollusks are bilaterally symmetrical and sluggish invertebrates (Apte 2015). Their size ranges from microscopic organisms to 20 m long. They are considered important ecosystem engineers to frame and protect the aquatic habitat’s bottom (Fortunato 2015). These animals play an essential role in stabilizing many marine ecosystems and keeping the algal and bacterial levels balanced. They play a crucial role in recycling nutrients, soil generation, and water filtration due to their abundance. Most bivalve members contribute to the organic turnover in the intertidal (littoral) zones of marine and freshwater ecosystems because of their active filtering. However, this filtering activity may also seriously interfere with the various invertebrate larval populations or planktons found suspended and free swimming in water. They also form an essential trophic level in the aquatic food chain and act as good bioindicators for the ecological quality in all types of aquatic habitats (Avila et al. 2000, 2004). Most members form food sources to a wide variety of other taxonomic groups like humans, birds, fish, mammals, and other invertebrates.

Mollusks play a crucial role in the lives of humans. They form a rich source of protein, good fat, and minerals (e.g., lime from the shells is used in poultry food and building material). In many regions, mollusk shells are used to manufacture ornaments and jewelry. This phylum plays a significant role in the pearl industry. Pearl oysters (*Pinctada margaritifera* and *P. mertensi*), which inhabit the Indian and Pacific Ocean's warmer parts along the coast of China, India, Sri Lanka, and Japan, form the most valuable natural pearls. Pearls are produced by most bivalves (pelecypods), including freshwater calms and marine oysters. When a small foreign object such as a particle of sand or parasite lodges between the shell and mantle, the foreign object becomes a nucleus around in which concentric layers of nacreous are laid by mantle to form a pearl (Avila et al. 2000).

A few members of this group are used as a medicine, especially for sore throat and cough. A recent research shows that a wide variety of secondary metabolites from mollusks possess anticancer, anti-inflammatory, and antimicrobial abilities. Most of these compounds are in clinical trials. The extracts from the shells and bioactive compounds of some mollusks act as growth inhibitors of cancer cells in mice (Beckendorf et al. 2005; Cohan et al. 2003).

Some mollusks, such as slug, shipworm, etc., act as pests and destroy garden and agriculture cultivations by eating leaves and cutting up roots and stems. Moreover, a few members of gastropod species are intermediate hosts for disease-causing parasites such as liver fluke (phylum Platyhelminthes, class Trematoda), which causes fascioliasis or liver rot in cattle. The zebra mussel *Dreissena polymorpha* is considered a harmful exotic invader. They were carried from Europe in ship ballast water to the Great Lakes and caused commercial damage by clogging the water pipes of power plants as well as cooling systems. They are driving many native freshwater bivalve species to extinction. Tereido worms, commonly called shipworms, burrow into the wooden structures immersed in the sea and cause severe damages to ships, piers, etc. (Avila et al. 2004).

## Mantle and Mantle Cavity

One of the unique features of mollusks is the presence of the mantle and mantle cavity. A thin fleshy double fold of tissue that lies beneath the shell and the part of the epidermis/skin is known as the mantle. This mantle secretes calcium carbonate layers, which form the mollusk's shell (Canti 2017) (Fig. 1). The mantle is rigidly

M

**Mollusk, Fig. 1** Mantle cavity. [http://www.mesa.edu.au/molluscs/molluscs\\_01.asp](http://www.mesa.edu.au/molluscs/molluscs_01.asp)

attached to the shell only at the outer edges and covers the visceral organs. The mantle also encloses a cavity called the mantle cavity between the mantle and the body. The mantle cavity functions as a respiratory chamber in most of the mollusks. The mantle's own exposed surface serves for gaseous exchange. In addition to that, the mantle cavity also possesses anus, osphradium, nephridia, and gonophores. So products from the digestive, excretory, and reproductive systems are emptied into the mantle cavity. In aquatic mollusk, there is a continuous water current, which kept moving by the surface of cilia or by muscular pumping, brings in oxygen and in some forms flushes out the food waste, and carries reproductive products (egg/sperm) out to the environment. In aquatic mollusks, the mantle is usually equipped with sensory receptors to detect the quality of environmental water current. In cephalopods, the muscular mantle and mantle cavity create a jet propulsion, which helps in locomotion. In cephalopods (squids and octopuses), the muscular mantle and its cavity create a jet propulsion used in locomotion. Many mollusks can withdraw their head or foot into the mantle cavity, surrounded by the shell, for protection.

## Shell

Mollusks possess a calcareous exoskeleton known as a shell, which encloses, supports, and protects their visceral organs. There is great variation in shell structure. The first shell appears during the larval period and grows continuously throughout life. Most of the members have an external shell, whereas the members, like a slug, cuttlefish, squid, etc., have an internal shell, but it is absent in octopus (Linstädter and Kehl 2012). The mantle secretes the shell made up of several layers consisting mainly of chitin and a protein hardened with calcium carbonate called conchiolin (Barnes et al. 2009).

Typically the shell consists of three layers (Fig. 2):

- a) The outer layer periostracum – It is the horny layer composed of an organic substance called conchiolin consist of quinone-tanned protein, which helps protect underlying calcareous layers from erosion by boring organisms. A fold of mantle edge secretes this, and growth occurs only at the shell's margin, and at the older parts of the shell, this periostracum often becomes worn out.

**Mollusk, Fig. 2** (a) Diagrammatic vertical section and mantle of a bivalve. (b) Formation of a pearl. [https://biocyclopedia.com/index/general\\_zoology/form\\_and\\_function02.php](https://biocyclopedia.com/index/general_zoology/form_and_function02.php)

- b) The middle layer prismatic layer, composed of densely packed prisms of calcium carbonate, is laid down in a protein matrix that is strengthened due to more calcium carbonate crystals made of columnar calcite. The mantle's glandular margin secretes this layer, and the increase in shell size occurs at the shell margin as the animal grows.
- c) The inner layer called the nacreous layer, made of laminated calcite, is responsible for pearl formation. This layer lies next to the mantle and is secreted continuously, so it increases in thickness during the life of the animal. The calcareous nacre is laid down in thin layers. Fragile and wavy layers produce the iridescent mother of pearl. A freshwater mollusk usually has a thick periostracum, whereas it is very thin, or in some members, it is absent in marine forms.

When a foreign body or microbe/stone enters and touches the mantle, the mantle's shell secretes cells that build up layers of the nacreous layer around it, and pearls are formed. To protect itself, the mollusk secretes the substance, a mineral called aragonite and conchiolin, a protein that is the same substance it secretes to form its shell. The composite of all these is called nacre or mother of pearl. The layers are deposited around the foreign body, and it grows over time, and a pearl is formed.

## Foot

The ventral body wall of mollusks is modified as a muscular foot. It varies in shape and function in different classes of mollusks. In gastropods, the foot is broad and expanded with a creeping sole. Rhythmic contractions of the muscular foot perform the locomotion. Moreover, the mucus-secreting glands present in the foot secrete mucus on which the animal slides. In bivalves (Pelecypoda), the foot is a large plow or wedge-shaped adapted for burrowing. A cephalopod's foot is used for jet propulsion, and the tentacles and arms are derived from the foot.

In polyplacophora, the foot is the broad flat muscular, glandular creeping sole and ventral in position. In scaphopods, the foot is long, narrow protrusible spade-like, and is used for digging. For mollusks such as limpets, the foot acts as a sucker attaching the animal to a hard surface (Kotpal 2009).

## Feeding and Digestion

Most members of this family enjoy intracellular digestion. The buccal cavity's interior region has a tongue-like organ called a **radula** (Fig. 3). The

**Mollusk, Fig. 3** Lateral section of a gastropod head showing the radula and radula sac. [https://biocyclopedia.com/index/general\\_zoology/form\\_and\\_function02.php](https://biocyclopedia.com/index/general_zoology/form_and_function02.php)

radula bears a ribbon of chitinous tooth-like ornamentation, supported by a muscular structure known as odontophore. The teeth are pointed backward. There are complex muscles that move the radula and its supporting cartilages. There may be a few or as many as 250,000 teeth. When the radula wears away, new rows of teeth are continuously replaced by secretion at its posterior end. The pattern and number of teeth in a row are species-specific. The movement of the radula is back and forth over the odontophore cartilage. During feeding, the animal opens the mouth; the odontophore is thrust forward, and the radula gives a strong scrape backward, brings food into the pharynx, and closes the mouth. This process is repeated rhythmically. The radula is generally used for feeding and is present in many species and serves to shred or scrape food like bacteria and algae of rocks. The mouth of mollusks is provided with slimy mucus-secreting glands to which the food particles are trapped. The trapped food enters the stomach by ciliary action in such a way that the mucus forms a long string called food string (Alison et al. 2020). The stomach has some acidic nature, which makes the mucus less sticky and frees the food particles from it, and reaches the structure called pyrostyle at the region of the hindgut. The pyrostyle is rotated by another set of cilia, which act as a bobbin and send the smaller particles, mainly minerals, to the pyrostyle to get excreted. Compared to the smaller particles, the large food particles are sent to the stomach's cecum for digestion and absorption. Excretory

organs consist of paired nephridia, which filter the waste products and open to the mantle cavity and push them out with the help of water current produced by ctenidia (Jordan and Verma 2001).

## Respiration

In mollusk, the process of gaseous exchange occurs through the body surface, particularly through the mantle and in specialized respiratory organs such as ctenidia, secondary gills, and lungs. Respiration in aquatic members of mollusks is performed by gills or ctenidia. The members of the terrestrial habitat perform pulmonary respiration. The feather-like gills are filamentous and provided with cilia. The ctenidia/gills are located on opposite sides of the mantle cavity and are arranged so that the cavity is functionally divided into an incurrent chamber and an excurrent chamber where the water enters through the bottom exit near the top (Fig. 4). There are three cilia sets, one set makes the water current into the mantle cavity, and two other sets keep the ctenidia clean. If the osphradia detects any unfavorable entry, the ciliary beating stops and prevents current water entry. The gills are supplied with blood vessels connected to the hemocoel (Jordan and Verma 2001). Cilia between gill filaments propel many leaf-like gill filaments project from the central axis, and water and blood diffuse from an afferent vessel in the central axis through the filament to an efferent vessel. The direction of

**Mollusk, Fig. 4** Respiratory system. [https://www.daviddarling.info/images3/bivalve\\_section.jpg](https://www.daviddarling.info/images3/bivalve_section.jpg)

blood flow is opposite to the water current, thereby establishing a counter current exchange mechanism.

## Nervous System and Organs of Sensation

In general, their nervous system has paired cerebral pleural, pedal, and visceral ganglia and simpler than annelids and arthropods. Typically a mollusk consists of a pair of cerebral ganglia (mass of nerve cells bodies) that innervate the head, mouth, and associated sense organs. Arising from the dorsal ganglia, two pairs of longitudinal nerve cords arise: a pair of lateral (pleural) nerve cords often forming pleural ganglia which innervate the mantle and a pair of pedal nerve cords that often include pedal ganglia which innervate the foot. In primitive forms, both nerve cords are interconnected by lateral branches of nerve fibers. A buccal nerve loop with paired ganglia generally supplies the radular apparatus in the head. Posterior paired visceral ganglia innervate the viscera. Because of torsion (twisting of the body during development), special nerve configurations are found in gastropods. In cephalopods, a cartilaginous capsule encloses the concentrated mass of ganglia. The cephalopods have two pairs of nerve cords with four paired ganglia. The visceral nerve cord serves the internal organs, whereas the pedal nerve cord serves the foot. The ganglia located above the esophagus are cerebral, pleural, and visceral, and the ganglia situated below the esophagus are the pedal (Jordan and Verma 2001). Monoplacophora and Aplacophora have a very primitive ladder-like nervous system (Fig. 5). The cephalopod members possess well-developed vertebrate-like eyes, and there are photoreceptors on the mantle margins of some bivalves.

## Circulatory System

Most mollusks' circulatory systems are mainly open type, where the blood or hemolymph pumps into the open space around the visceral organs and nourishes the visceral organs. As

**Mollusk, Fig. 5** Nervous system of gastropods. [https://commons.wikimedia.org/wiki/File:Gastropod\\_nervous\\_system.gif](https://commons.wikimedia.org/wiki/File:Gastropod_nervous_system.gif)

mollusks are true coelomates, the main body cavity is called hemocoel, through which the coelomic fluid and blood circulate (Pechenik 2015). The hemocoelic spaces act as a hydrostatic skeleton. The heart possesses one or two atria/auricle pairs that receive the gills' oxygenated blood and pumps it into ventricles. From there, it enters into the main blood vessel called the aorta that opens into the hemocoel. The auricle/atria perform the excretory system's function partly by filtering waste products out of the blood and dumping them into the coelom as urine (Ruppert et al. 2004). The body fluids are transported largely within sinuses devoid of distinct epithelial walls; the heart is posterior-dorsal, enclosed in a pericardium that typically consists of a ventricle and two posterior auricles. The blood or hemolymph is drained from ctenidia, gills, or the specialized respiratory epithelia into respective chambers. The ventricle pumps the hemolymph through the middorsal sinuses (in solenogasters and scaphopods) or vessel (aorta) into the body tissues. Hemocyanin is the respiratory pigment that contains copper rather than iron: in more advanced forms, hemoglobin is bound to blood

**Mollusk, Fig. 6**

Circulatory system

cells. In chiton and some members of monoplacophorans, the heart is also the site of purification discharged waste into the pericardium and via a pair of pericardial outlets (modified kidney/nephridia) (Fig. 6).

## Excretory System

The anatomical structure of the renal gland varies from species to species. Still, a common plan is evident. The atria/auricle of the heart also functions as part of the excretory system by filtering waste products known as the organs of Bojanus. The renal gland is a relatively wide tube opening from a sac (pericardium) that surrounds the heart at one end and to the mantle cavity at the other end. Some mollusks possess Keber's organ, otherwise called the pericardial gland. It is a large reddish-brown glandular mass situated anterolateral to the pericardium into which the waste materials are excreted. A majority of mollusks are aquatic, so they excrete nitrogen in the form of ammonia (Baeumler et al. 2012). In octopus the excretion is in the form of ammonium chloride. Terrestrial snails and slugs excrete uric acid and excrete ammonia when the animal is in moist surroundings. In all mollusks, the primary urine production appears to be filtration of blood. This may take place through the heart walls into the pericardium or from blood vessels that supply the glandular part of the renal gland. These are located

at the rear of the coelom, extract any reusable material from the urine, dump additional waste products into it, and then eject it via tubes that discharge into the mantle cavity (Brusca et al. 2014). In most freshwater mollusks, the reabsorption process takes place by glandular tube and in the wide tubule. So the final urine is more dilute than the blood.

## Reproduction

Most mollusks are dioecious, and fertilization occurs externally, except terrestrial mollusks such as snails, slugs, and cephalopods (Furuhashi et al. 2009). In adult cephalopods and other representatives, the paired dorsal gonad retains the developmental connection with the pericardium. Some solenogasters egg and sperms are discharged into the pericardial cavity and through pericardial outlets discharge to an environment where the fertilization takes place. In more advanced mollusks, separate gonoducts (oviducts for female gametes vas deferens for male gametes) produce the egg and sperm respectively to the mantle cavity. In some mollusks, the zygote hatches and undergoes two larval stages – **trochophore** and **veliger** – before becoming a young adult; bivalves may exhibit a third larval stage, **glochidia**. Eventually, the larva sinks to the seafloor and metamorphoses into an adult form (Buchsbaum et al. 2013).

**Mollusk, Fig. 7** *Pila*.

### Classification of Phylum Mollusca

There are seven living classes and two extinct groups. First, we will see the living classes:

1. **Gastropoda** (Gr. *gaster*-belly+*podios*-foot): This is the largest class of mollusks and includes snails, conchs, abalones, and whelks sea hares, garden slugs, etc. Because their stomach is situated on foot, they are named gastropods. The member's habitat includes marine, freshwater, or terrestrial. Their body is asymmetrical with a distinct head, which is well developed with tentacles and eyes. The foot is broad and expanded with a creeping sole. Rhythmic contractions of the muscular foot perform the locomotion. Some mucus-secreting glands in the foot secrete mucus on which the animal slides (Ruppert et al. 2004). The body is asymmetrical due to the "rotation of visceral mass in its axis" (torsion). There is a lid at the opening of the shell called the operculum. Respiration is by gills or pulmonary sac. The mantle encloses the visceral mass. The buccal cavity contains the radula with odontophore, which works as a file to scrape and tear food materials. The nervous system is well developed with paired ganglia and their connectives and commissures, with distinct cerebral and pleural ganglia besides pedal and visceral ganglia. Sexes are separate, and the development is indirect through a veliger larva or trochophore larva. The animal is very active during the night or dim light. As the

slugs have no shell, the mucus layer gives protection to the body, enabling the animal to live in wet and moist areas. Slugs and land snails cause severe damage to plants and agricultural cultivations as they eat leaves and stems (Jordan and Verma 2001; Louise 2006). Examples include *Pila* (Fig. 7), *Xancus*, *Aplysia*, *Doris*, and *Dolabella*.

2. **Pelecypoda (Lamellibranchiate or Bivalvia)**: Pelecypodes (Gr *pelekus*-hatchet+*podos*-foot) are bilaterally symmetrical, laterally compressed mollusks with a two-lobed mantle. The body is enclosed within two valved shells, hence the name bivalve. The head is rudimentary without eyes and tentacles but with a pair of labial palps. The foot is large plow or wedge-shaped, adapted for burrowing. The respiratory organs are plate-like gills called ctenidia. The intestine is highly coiled and devoid of the radula. Excretory organs consist of paired nephridia. The nervous system includes three pairs of nerve ganglia – cerebropleural, pedal, and visceral (Ruppert et al. 2004). Sexes are separate, gonads are single, and development includes a parasitic glochidium larva (freshwater mussel) or free-living veliger larva (Pinctada). This group includes clams, oysters, and scallops. They are the food sources for other living beings, including humans. This group of animals is well adapted for living in the water. For protection, clams burrow deep into the sand by contracting and relaxing their muscular foot. Mussels and oysters attach themselves with a

**Mollusk, Fig. 8** Pinctada. [https://en.wikipedia.org/wiki/Pinctada#/media/File:Pinctada\\_margaritifera\\_MHNT.CON.2002.893.jpg](https://en.wikipedia.org/wiki/Pinctada#/media/File:Pinctada_margaritifera_MHNT.CON.2002.893.jpg)

strong thread or cement to solid surfaces, called byssus threads. Examples include *Lamellidens*, *Milieus/Perna*, *Pinctada* (Fig. 8), and *Solen*.

3. **Polyplacophora (Loricata or Amphineura)** (Gr. Amphi-both+nervous-nerve): This group is considered as most primitive of existing mollusks. The members of this group include chitons. They are exclusively marine, bilaterally symmetrical, and dorsoventrally flattened animals. They have an articulated shell composed of eight hinged and overlapping longitudinal/transverse plates or valves (Budd and Jensen 2000). A thick leathery mantle covers the body. They have an indistinct head without eyes and tentacles. They have a well-developed radula mounted on an odontophore. The foot is the broad, flat muscular, glandular creeping sole and ventral in position. The mantle cavity is restricted to mantle grooves on either side of the ventral side. Numerous bipectinate gills occur on either side of the body in the mantle groove. The nervous system is primitive and ladder-like, which resembles the Platyhelminthes (turbellarians). They have

a cosmopolitan distribution, from cold waters through to the tropics (Jordan and Verma 2001). They live on hard surfaces, such as on or under rocks or in rock crevices, inhabit intertidal or subtidal zones, and are exposed to the air and light for long periods. They feed on algae and seaweeds that grow on rocks by their radula. Examples include *chitons* (Fig. 9), *Leptochiton*, and *Chaetopleura*.

4. **Cephalopoda** (Gr kephale-head+podos foot): The word cephalopod means “head-footed.” All are exclusively marine, most specialized, and complex animals such as squid, octopuses, and cuttlefish. The members possess a large head, a crown of oral arms, a well-developed nervous system with centralized brains, and large eyes similar to the human eyes. They are the only mollusks having an advanced circulatory system, an accessory bronchial heart, and closed blood vessels. Their foot is divided into many tentacles with strong suction cups or hooks, capturing the prey. They feed on crustaceans, worms, and other small mollusks (Canti 2017). They have thick muscular, and

**Mollusk, Fig. 9** Chiton. <https://www.flickr.com/photos/jsjgeology/15947947127>

**Mollusk,**

**Fig. 10** Octopus. [https://www.flickr.com/photos/joachim\\_s\\_mueller/6775462987](https://www.flickr.com/photos/joachim_s_mueller/6775462987)

M

leathery mantle. There is an external or internal shell, which can be absent in some species. They have a cartilaginous endoskeleton for supporting the body, attachment of muscles, and protection of nerve centers. They possess ink glands as a defensive adaptation. These glands secrete melanin-containing dark color ink to discolor the surrounding water and escape enemies (Stoger et al. 2013). Examples include *Sepia*, *Loligo*, *octopus* (Fig. 10), and *Nautilus*.

5. **Scaphopoda (Solenoncha):** Scaphopoda (Gr. Shapha-boat+podos-foot) includes elephant tusk shells. A group of aberrant marine mollusks of very low grade of organization. According to the fossil record, it is believed that scaphopods from the youngest mollusks and appeared from Mississippian onwards. The members of this class are exclusively marine. The shells' size ranges from about 0.5 to 15 cm in length, and they like to live in soft substrates offshore. Long cylindrical and

bilaterally symmetrical body without eyes, sensory tentacles, and gills (David and Winston 2001). Tubular and tusk-like shell open at both ends. Mantle edge fuses to form a mantle tube open anterior and posterior. The foot is long, narrow protrusible spade-like and is used for digging. The mouth is surrounded by lobular outgrowths, cephalic filaments, or protrusible tentacular processes called captacula, which serve as tactile organs to capture food particles. As gills are absent, the respiration is by the exchange of gases through the mantle surface. The circulatory system is simple, and the heart is rudimentary or absent. The nervous system has a pair of cerebral and pleural ganglia. Sexes are separate, and development includes a veliger larva. According to molecular data, it is suggested that the scaphopods are considered Cephalopod sister group (Ruppert et al. 2004). An example is *Dentalium* (Fig. 11).

6. **Aplacophora:** Aplacophora is the animal group popularly known as Solenogasters or mud moles. They are primitive degenerative marine mollusks that inhabit marine habitat with cosmopolitan distribution with long, narrow, bilaterally symmetrical, and vermiform bodies (Scheltema 1993). There is the absence of head, foot, mantle, shell, and nephridia (Ruppert et al. 2004), but they have calcareous spicules in the skin. The digestive tract is straight with toothed radula in the mouth. They have the presence of a pair of

coelomoducts, which serve as gonoducts. The heart consists of a single auricle and a ventricle. Hemocoel has two portions, namely, dorsal hemocoel and pedal hemocoel separated from each other by septum. The aplacophorans are traditionally considered as an ancestral mollusk (Buchsbaum et al. 2013). They are found at all depths of the sea, usually absent in the littoral zone. Some of them burrow in the mud while some are live in association with certain colonial coelenterates, and still, others are predators. The group comprises the two clades Solenogasters and Caudofoveata. The aplacophorans are traditionally known as ancestral mollusks (Budd and Jensen 2000; Amelie 1993). Examples include *Neomenia* (Fig. 12) and *Chaetoderma*.

7. **Monoplacophora (Tryblidiida):** A small group of mollusks with primitive features. Body bilaterally symmetrical flat and oval body with a minute head foot, mantle, and radula. The body is internally segmented. The shell is univalved, conical or cup-shaped, and symmetrical. There is the presence of segmentally paired external gills, segmentally repeating nephridia, and gonads. They have a primitive ladder-like nervous system. The sexes are separate in almost all forms. At present, a monoplacophoran is represented by a single genus, namely, *Neopilina*. It is a very primitive form and considered a living fossil and thought to have become extinct over 380 million years ago. The shells of many

**Mollusk, Fig. 11** Dentalium. [https://commons.wikimedia.org/wiki/File:Dentalium\\_octangulatum\\_01.JPG](https://commons.wikimedia.org/wiki/File:Dentalium_octangulatum_01.JPG)

*Neopilina*. [https://digit.snm.ku.dk/www/inv/full/MON-000001\\_shell-mo.jpg](https://digit.snm.ku.dk/www/inv/full/MON-000001_shell-mo.jpg)

monoplacophorans are limpet-like in shape. They were not recognized as such until 1952 (Ruppert et al. 2004). An example is *Neopilina* (Fig. 13).

**Some Extinct Groups of Mollusks**

- a) **Rostroconchia:** These are extinct mollusks from the early Cambrian period to the late Permian period. This group was mistaken as bivalves because the larval stage is univalve, but the adult typically has a pseudo-bivalve shell that encloses the mantle and muscular foot. This group consists of more than 1,000 species of members (Budd and Jensen 2000).
- b) **Helcionelloida:** They are also an extinct group of mollusks, consisting of the oldest

conchiferan mollusk with mineralized shells (Budd and Jensen 2000).

**The Fossil Records**

Mollusks are considered some of the oldest metazoans. The evolutionary history and origin of mollusks from the ancestral group Lophotrochozoa and their evolution into modern living form and fossil form are still a debated subject. Some of the fossil record obtained from the south region of Australia and North Russia shows close resemblance with mollusks. There is good evidence available for the appearance of gastropods and bivalves (Parker 2017). Most familiar members of living members of this phylum, such as the Gastropoda, the Bivalvia Cephalopoda, the

Polyplacophora, the Scaphopoda, the Monoplacophora, and the Aplacophora are believed to originate from the Cambrian period (Budd and Jensen 2000). Now itself, the debate occurs about *Kimberella*, a mollusk-like organism from 555 million years ago, and some Ediacaran and early Cambrian fossils (Ruppert et al. 2004).

## Synonyms

[Ecdysis](#); [Eclosion](#); [Shedding](#)

## Definition

The process of casting off outer coverings.

## Introduction

Protection from the constant assault of environmental harms is a basic need of all living organisms. Whether they are physical or biological,

such challenges pose a threat to survival. Defense takes shape in the way of barriers like skin, scales, feathers, and hair which shield the inside environment from the outside one. Like all defenses, these “suits of armor” incur costs to maintain integrity and consequent effectiveness. Skin cells die and are constantly shed and replaced, feathers are lost and new ones grow in, and likewise scales and hair are renewed. Instead of such constant and gradual turnover, some vertebrate animals shed their entire protective covering abruptly as when a snake or frog sheds its skin, or a bird changes plumage. In contrast, most invertebrate animals – lacking an internal skeleton – are encased in a protective coating called an exoskeleton that is very durable and frequently hard in texture. There, growth and renewal happens only through the process of molting, also known as ecdysis, when the entire covering is shed in a single event. Molting has been recorded as far back as the Cambrian in fossils of early arthropods (García-Bellido and Collins 2004). The diverse groups of invertebrate animals that molt their exoskeletons are collectively named the Ecdysozoa (Aguinaldo et al. 1997).

## Molting and Molt Phases

Exoskeletons are effective shields and vary in ways they function as skeletons. They can form points of attachment for muscles or function solely to maintain an animal’s shape. As with all adaptations that increase survival, there are trade-offs, and for being coated with an effective nearly impenetrable encasement, one trade-off is more limited motion and flexibility. Perhaps most importantly, exoskeletons restrict growth because such coatings cannot gradually and continuously stretch and expand. Therefore arthropods such as insects, crabs, shrimps, and lobsters as well as other ecdysozoans, the nematodes, nematomorphans, kinorhynchs, priapulids, onychophorans, and tardigrades must molt in order to grow. This limitation has obvious implications for overall size but also a less apparent consequence: mouthparts eventually become too small for efficiently meeting an animal’s increasing

energy demands and need to be included in the molting process. Having said that, molting may not always be associated with growth in all ecdysozoans since some species of tardigrades can be smaller after molting when they are starved beforehand (Baumann 1961).

Among insects and crustaceans, the entire molting process consists of three phases, premolt, molt, and post-molt with behavioral changes associated with each. In general, preparations for ecdysis occur during the premolt phase when the muscular connections to the old exoskeleton loosen and the exoskeleton cracks along defined lines called sutures. The molt phase follows with the animal wiggling out of the old exoskeleton. During the post-molt phase, the animal swells in size and the new soft exoskeleton sclerotizes. Until such hardening completes, some crustaceans are supported by a hydroskeleton (Taylor and Kier 2003). As Ecdysozoa are a diverse animal group, duration and complexity of molt phases vary greatly among members. For example, the entire molting process is accomplished in a matter of hours for nematodes (Singh and Sulston 1978) but can take as long as 16 weeks in some land crabs (Fletcher et al. 1990). Changes in physiology during molting are complex, as are some of the behaviors associated with them discussed next.

## Molting Hormones and Behavior

The cellular changes during premolt, molt, and post-molt phases are orchestrated by a variety of molting hormones. Best studied are the ecdysones and juvenile hormones of arthropods, major hormones involved in growth, molting, and metamorphosis, which appear to be structurally and functionally similar to thyroid hormones (Flatt et al. 2006). These hormones and their analogs might be expected in some other ecdysozoans, as in the case of the onychophoran *Euperipatoides leuckarti* (Hoffman 1997). And still, free-living nematodes lack ecdysteroids (Chitwood 1999), and no orthologs of ecdysone receptors are found in the complete genome of *Caenorhabditis elegans* (Sluder and Maina 2001). Genetic

evidence supports the idea of an endocrine control for molting in *C. elegans* (Frand et al. 2005), so some other steroid(s) must be involved as inferred by the requirement for cholesterol to molt successfully (Yochem et al. 1999).

Molting hormones can produce neurophysiological effects on behavior. Among insects, feeding stops, and locomotor activity declines with decreased juvenile hormone or a surge of ecdysterone near the onset of the molt phase (Raabe 1982). The premolt loosening of connections to the exoskeleton and shedding of the old exoskeleton by peristaltic contractions during the molt phase are regulated in insects by a neuropeptide cascade (Gammie and Truman 1997). Similar to insects, crustacean molting appears to be regulated by neuropeptides. Behavioral features of molting similar to those of insects (positioning, wiggling, shedding) are correlated with a rise and fall of crustacean cardioactive peptide (Phlippen et al. 2000). In lobsters, increased levels of aggression and greater inclination toward escape characterize pre- and post-molt behavior, respectively (Cromarty et al. 1991). Presumably, these behavioral changes are under hormonal regulation.

## Molting and Predator Avoidance

When the protective function of the exoskeleton is considered, the vulnerability of an animal to environmental attack during molting is immense. The loss and reformation of an exoskeleton is physiologically challenging, energetically expensive, and time consuming. By losing their protective shell, a molting animal must endure a period of time, often days, when it is soft-bodied and defenseless. Moreover, such animals have limited mobility since most of its musculature for locomotion is attached to the exoskeleton. Therefore, molting animals cannot escape or show aggression toward an attacker. To survive the process of molting, many animals have evolved adaptations for protection. For example, some animals become cryptic through adaptations that are physical, behavioral, or both. In all cases known, establishing some form of protection during

premolt is crucial, and there are a variety of ways safety can be achieved.

Vulnerability to attack during molting is most commonly thought of in terms of visual predators, and these might be deterred by camouflage or concealment. So, for example, premolt caterpillars of moths and butterflies often search for protected out-of-view microhabitats like the undersides of leaves for building camouflaged cocoons or attachment spots for pupation from chrysalides (James and Nunnallee 2011). Concealment underground has evolved in a diversity of species that establish burrows during premolt. For example, some caterpillars of moths drop from host plants to burrow underground and molt (Janzen 1984), as do hymenopteran caterpillars (Smith and Janzen 2003). Coconut crabs, *Birgus latro*, seek out soft ground away from their usual rocky habitats to dig molting burrows, which can be 1 m long at 0.5 m depth (Fletcher et al. 1990). Finally, nocturnal molting is common among a number of insects (Lindgren and Wolf 1982; Wallace and Anderson 1996).

Many predators are not so visual and instead use scent to find their food. Prey have evolved adaptations for chemically cloaking their location, a strategy particularly effective during molting. For instance, some caterpillars incorporate chemicals from their food plants that make them chemically “invisible” to predaceous ants (Akino et al. 2004). Larvae of the European lycaenid butterfly species *Maculinea rebeli* are inquilines or tenants that live and molt in *Myrmica* ant nests while disguised as chemical mimics (Dettner and Liepert 1994). Chemical adaptations for protection can also be defensive as in *Pycnogonum littorale*, a sea spider that releases molting hormones, ecdysteroids, to deter predators before and during molting (Tomaschko 1994).

Lobsters, *Homarus americanus*, have evolved adaptations that physically, temporally, and chemically decrease vulnerability during molting. Lobsters are nocturnal and seek cover during daylight hours in shelters they excavate in rocky areas. In the weeks prior to molting, a lobster utilizes more than one shelter, which it barricades with carefully selected rocks, pebbles, and seaweeds. Lobsters molt in the early morning allowing them time to

start hardening their shell before the next nocturnal activity period when other lobsters can find and evict them. Once outside the shelter, they are vulnerable to predation. In the first post-molt days, they can hardly walk and avoid fights by jetting away. It may take a male several months to regain his old dominance status despite the fact he is now much larger than before molting. Mature females employ a remarkable strategy for survival and reproduction: they join a dominant male in his shelter by emitting a pheromone that subdues his natural aggression to any other lobster who tries to enter (Atema and Steinbach 2007). The pair cohabits for several days during which he inseminates and protects her when she molts. This gives her time to harden her new shell, and it reduces chances for other males to inseminate her. The dominant male practices serial monogamy and can receive a series of premolt females, one at a time (Cowan and Atema 1990). When his own time to molt arrives, he has no protection and drops down the dominance hierarchy.

## Molting and Feeding Behavior

Many ecdysozoans do not feed immediately following molting. This post-molt delay lasts until their mouthparts harden (Greenway 1985). The length of time varies widely for a group as diverse as the Ecdysozoa, and focusing on its composite phyla does not help to narrow the variation. For example, among the Crustacea, feeding can resume within 24 h to a week following ecdysis (Steel 1982; Greenway 1985). Their first meal is usually the old exoskeleton, the exuviae, which are consumed to replenish calcium stores and other minerals (Paul and Sharpe 1916; Auzou 1953; Steel 1982; Graf 1978). In lobsters (*H. americanus*), the male consumes the cast shell of his cohabiting female (Atema, personal observation). Fletcher et al. (1990) speculate that much of the 3–4 weeks before coconut crabs emerge from molting burrows is occupied by the consumption of the old exoskeleton. Not all ecdysozoans eat their exuviae. For example, the nematode *C. elegans* does not eat its old exoskeleton yet begins feeding as soon as it molts and

begins crawling out of its old cuticle (Singh and Sulston 1978). While feeding is delayed in the priapulid *Priapulius caudatus* for nearly a week, the exuviae are not consumed presumably because it does not contain essential minerals like calcium (Trott 2017).

## Conclusion

All animals have a protective coating to shield them from the environment. For ecdysozoans, that barrier restricts growth, and increase in size comes with the expense of shedding their exoskeleton in its entirety through the process of molting, a complex process requiring physiological and behavioral changes, orchestrated by a variety of hormones. The Ecdysozoa encompasses a diverse group of invertebrates, which are equally diverse in their behavioral adaptations required to survive a most vulnerable time in their life histories. These include visual and chemical concealment from predators and frequent use of burrowing which accomplishes both. A cyclic physiologically and physically transformative process, filled with chances for failure, molting is certainly one of nature's amazing evolutionary wonders.

## Synonyms

[Pair-bonding](#); [Pair-living](#)

## Definition

A mating system in which two individuals consistently and primarily mate within their pair.

## What Constitutes Monogamy?

Monogamy is a mating system in which two individuals consistently and primarily mate within their pair. Measuring the consistency and exclusivity of monogamous pairs can be challenging, and there is currently a lack of agreement regarding what frequency of extra-pair copulations, if any, should still constitute a monogamous mating system. Accordingly, while this system is often associated with pair-living and pair-bonding, these arrangements do not necessarily indicate monogamy. Pair-living, also referred to as social monogamy, is a social organization in which two adults of opposite sex occupy the same home range with their nonreproducing offspring. Pair-bonding represents a long-term social relationship between two unrelated individuals of the opposite sex which is characterized by affiliative interaction, close proximity, and reciprocity (Tecot et al. 2016).

## Distribution and Prevalence

Throughout the animal kingdom, monogamous species are relatively rare compared to those characterized by other mating systems. This pattern is expected because, in most species, males have access to several breeding females, and offspring can survive without paternal care. In such contexts, males can increase their reproductive success (i.e., number of offspring) by associating and mating with more than one female. Thus, monogamy is not an advantageous mating strategy for males of most species (Trivers 1972).

Lifelong monogamy is particularly rare among pair-living animals, which typically practice serial monogamy. In the latter case, monogamous bouts

are separated by divorce, which is defined as having occurred when both previously paired individuals are alive during a subsequent breeding season and at least one of them consistently mates with a new partner. Divorce has evolved as an adaptive behavioral strategy since it is triggered by low breeding success (relative to other individuals of their species) and often results in increased breeding success for the initiating individual (Culina et al. 2015). Divorce rates vary across species and usually increase as adult sex ratios become more skewed. In humans, divorce rates peak at 4 years of marriage. This may reflect an adaptation to serial monogamy in which the pair-bond duration is similar to the age at which infants are weaned (Fisher 1989).

Interestingly, the prevalence of monogamy varies greatly between animal groups. While 90% of bird species are classified as socially monogamous, this is true for only 9% of mammals (Lukas and Clutton-Brock 2013). This difference is likely to be driven by disparities in infant care and parental investment. In mammals, only mothers can provide nourishment for nursing offspring. Consequently, a lack of paternal investment is less costly to mammalian offspring survivorship, and mammalian males can benefit relatively more from investing in mating rather than parenting (Opie et al. 2013). Furthermore, in contrast to socially monogamous birds, extra-pair mating is relatively low in socially monogamous mammals. This is likely to reflect adaptations to bi-parental care and/or mate guarding (Lukas and Clutton-Brock 2013). Infidelity rates are higher for bird species which nest in colonies, as colony-dwelling individuals have more opportunities to find a mate of higher quality than their partner (Moller and Birkhead 1993).

Primates are unusual among mammals in that approximately 29% of species are monogamous (Lukas and Clutton-Brock 2013). This mating system has evolved independently in all major primate clades (Opie et al. 2013). Humans represent an interesting case, as about 17% of human cultures are considered monogamous,

meaning that in these cultures, polygyny is either prohibited or extremely rare. However, although the remaining majority of human societies exhibit slight or general polygyny (Marlowe 2000), most marriages within those societies are nonetheless socially monogamous (Dixson 1998).

## Evolutionary History

The selective pressures that lead to monogamy are still debated. Male infanticide may lead to monogamy, with protection against infanticidal rivals selecting for paired males who can offer protection to offspring. This may explain the high prevalence of monogamy in primates, since they are relatively altricial and exhibit long lactation periods, which can increase infant vulnerability to infanticide (Opie et al. 2013). Furthermore, although most mammals are seasonal breeders, many primate species reproduce all year round. Nonseasonal breeding increases the likelihood of infanticide since females in these species can be brought back into estrus sooner following the loss of an unweaned infant. Monogamy may have also evolved as a way for males to secure access to females who are dispersed due to low food density. This could also explain the high frequency of monogamy in primates since many species depend on high quality, low abundance food resources (Lukas and Clutton-Brock 2013). Other theories have been proposed to explain the evolution of pair-living and/or pair-bonding, but such ideas do not necessarily explain monogamous mating. These include predation-driven optimal group size and resource defense (Tecot et al. 2016).

Many monogamous species have subsequently evolved cooperative breeding or paternal care (Lukas and Clutton-Brock 2013; Opie et al. 2013). In cooperative breeding systems, females usually stay in their natal group and, rather than producing their own offspring, provide care for the offspring of their dominant relatives. Since

monogamy increases sibling relatedness, this makes cooperative breeding potentially beneficial for nonbreeding individuals (Lukas and Clutton-Brock 2013). Monogamy also provides the opportunity for paired males to provide infant care, which can decrease parenting costs for females. This may allow females to increase resources dedicated to lactation, potentially leading to shorter lactation periods, shorter inter-birth intervals, and higher reproductive rates. Consequently, paternal care can improve the reproductive success of both males and females in monogamous species (Opie et al. 2013).

## Neurobiological Mechanisms

Neurobiological studies on monogamous organisms have identified the proximate mechanisms underlying monogamy. Pharmacological and neuroimaging studies have identified the involvement of specific brain areas, such as the nucleus accumbens, lateral septum, and ventral pallidum. These regions are associated with reward processing and stress responses. Key neurotransmitter systems have also been identified which are critical in the formation and/or maintenance of pair-bonds. These include dopamine, opioids, oxytocin, and vasopressin. Across taxa, these systems are associated with regulating sociosexual behavior and reward learning (Johnson and Young 2015).

Most of our current knowledge regarding the neurobiology of monogamy is the result of laboratory studies of monogamous prairie voles (*Microtus ochrogaster*). Individuals of this species form long-term social bonds with their mates and produce multiple litters in these pairs. However, within populations, not all prairie voles exhibit the same inclination for monogamy. Interindividual neurobiological differences have been linked to the observed differences in pair-bonding behavior. Furthermore, a closely related species, the montane vole (*Microtus montanus*), is asocial and promiscuous. Comparative studies of these species have illuminated the neurobiological differences underpinning this mating

behavior variation. This work has facilitated studies in other monogamous animals which are also relatively easy to maintain and breed in laboratory settings. These include species of primates (titi monkeys: *Callicebus cupreus*; marmosets: *Callithrix penicillata*), birds (zebra finches: *Taeniopygia guttata*), rodents (deer mice: *Peromyscus californicus*), and fish (cichlid fishes: *Amatitlania nigrofasciata*). Overall, these studies suggest an evolutionarily conserved role for many neurotransmitters in modulating monogamy-related behaviors (Johnson and Young 2015).

## Definition

A monophyletic group is a set of taxa descended from a single (“stem”) taxon (*i.e.*, a ► [common ancestor](#)), which includes all taxa descended from this single common ancestor, as well as the ancestor itself. Monophyletic groups are defined by the sharing of apomorphic (“derived”) conditions and, for that reason, the taxa contained in a given monophyletic group are considered more closely related to each other than to any taxon classified outside of this group.

## Introduction

Phylogenetic systematics (or Cladistics) is a field in biology that aims to reconstruct the evolutionary history and patterns of relationship among extant and fossil organisms. It consists of a method of character analysis for studying the evolution and relationships among organisms based on observed heritable characteristics (phenotypes or genotypes), which are tested under specified models of evolution. The results of a phylogenetic analysis are represented by a ► [phylogeny](#) (or phylogenetic tree), which graphically symbolizes the evolutionary history of a group of taxa. Phylogenetic trees are obtained through a congruence analysis (like ► [parsimony](#), maximum likelihood, or Bayesian inference), their tips represent the “end” or the “present time” in an evolutionary lineage and are constituted by the terminal taxa that are being studied (either extant or fossil organisms). The pattern of connections between

these taxa hypothesizes the phylogenetic relationships among them.

Phylogenetic systematics was first proposed by Emil Hans Willi Hennig (1950, 1966, 1968) as a biological reference system that not only investigates and expresses the evolutionary relationships among organisms but also offers a rationalization of the phenomena leading to these relationships. Hennig's initial step was to consider an individual organism in a specific period of its life history—named semaphoront—as the fundamental unit of systematics. This individual would be the “character-bearing specimen,” which is an organism in a definite, brief interval of its life span (Hennig 1966). His proposition was based on the evidence that the morphology of a given individual could not only vary when compared to different taxa but also as a function of time (ontogeny) and in various lineages, as among sexes and between seasons

(Hennig 1966; Sharma et al. 2017). Therefore, Hennig established the idea of semaphoront as a solution to standardize the interval in life in which the specimens representing the different taxa in a phylogenetic analysis should be studied. In order to make valid comparisons, taxa selection for phylogenetic analyses should preferably contain comparable semaphoronts (*i.e.*, individuals sharing similar ontogenetic stages, sex, etc.). According to Hennig (1966), semaphoronts would be connected by ontogenetic relationships and form individuals; individuals by tokogenetic (*i.e.*, population genetic or genealogical) relationships and form species; and species by phylogenetic relationships, represented as cladograms (Fig. 1). From these, only the phylogenetic relationships among semaphoronts would constitute a “hierarchic system,” in the mathematical sense, and thus be used for biological classification purposes as a result of phylogenetic analyses.

**Monophyletic, Fig. 1** Modification of figure 6 of Hennig (1966), indicating the differences between ontogenetic, tokogenetic and phylogenetic relationships. Colored

individuals exemplify the origin and maintenance of an apomorphic state for a certain character

The relationships between the different hierarchies contained in a phylogenetic tree are determined by the existence of shared novel characteristics (**apomorphies**) between the analyzed taxa (Fig. 1). These characteristics are acquired during the phylogenetic separation of a common ancestor into two taxa, and kept in the new population by means of tokogenetic relationships among its individuals. Natural groups are delimited by apomorphic characters states and called **monophyletic** groups. It is important to note that it is not enough for organisms to share characteristics; in fact, two organisms may share several characteristics and still not be considered members of the same, less inclusive, group. That is because these characteristics may represent unmodified features (**plesiomorphies**) inherited from their ancestors, and sharing of these with other phylogenetic hierarchies is not used as evidence of phylogenetic relationships.

Below, we provide detailed explanations of a few topics in order to further explore the presented concepts.

### What are *Characters* and *Character States* in a Phylogenetic Systematic Context?

Despite the term “character” being central to phylogenetic analyses, its precise meaning was often neglected in theoretical phylogenetic studies. This was changed in 2007, after the publication of a revisionary study by Paul Sereno. His study focused on the logical basis for morphological characters and provided formal definitions for the terms *characters* and *character states* to be used in a phylogenetic systematics’ context. Sereno (2007) proposed that **characters** should be the term applied for *independent variables* (i.e., ► [Homology](#) parts that vary across the different semaphoronts), while **character states** should be *mutually exclusive conditions* of a given character (i.e., different ways in which a specific character may vary). For example, when studying the different ways that the anterior limb of mammals may vary, the independent variable (thus, the character) would be *anterior limb*, and the exclusive conditions (character states) are the different ways in which this character is observed:

as a *wing* (in bats), as *fins* (in aquatic mammals), as *arms* (in apes), or as the *front legs* (in quadrupeds).

The necessity of a formal definition comes from the confusion caused by the interchangeable operational use of the terms “character” and “character state,” which started with Hennig (1966), but persisted in several subsequent works (e.g., Platnick 1979; Patterson 1982). In the pursuit of well-delimited definitions, Sereno’s (2007) circumscriptions of *character* and *character state* are used hereafter.

### Natural Groups of Species and Evolution

The basic idea behind phylogenetic systematics is that members of a certain hierarchy group share a common evolutionary history. They are more “closely related” to members of the same group than to other organisms, because they share unique characteristics that were not present in distant ancestors. The term **natural group** describes these groups of taxa that exist in nature and are connected hierarchically by past evolutionary events.

Despite our ability (or lack thereof) to recognize natural groups, we accept a single origin for life on earth. Thus, all organisms are related to each other in some way or another and, because of that, we can retrieve the pattern of relationships among any organisms. We only have to use the right kind of information in order to do so. In this sense, the phylogenetic system tries to provide an idea of how these natural groups are connected and hierarchically organized by successively shared common ancestors. These groups are subordinated one to the other according to the temporal distance between their origins and the present time, and the sequence of subordination corresponds to the recency of common ancestry (Hennig 1966).

These natural, hierarchically disposed groupings are named **monophyletic** groups. A monophyletic group is a set of taxa descended from a single (“stem”) taxon, and which includes all taxa descended from this stem’s common ancestor, besides the ancestor itself (Hennig 1966). Therefore, every terminal taxon contained in a given monophyletic group is considered more closely related to each other than to any taxon classified outside of this group. Recognition

of monophyletic groups requires identification of characteristics that demonstrate the sequence of temporal subordination among those groups.

### Apomorphic and Plesiomorphic Character States in the Understanding of Natural Groups

Evolution is a transformation of organisms through which the descendants accumulate differences from their ancestors. Consequently, the split of a given taxon into two mutually isolated communities (cladogenesis) implies the existence of a transformed (“changed”) character state in at least one of the daughter taxa (Hennig 1966) (otherwise, those communities would not be different). This transformed character state, shared by the new community, is termed **apomorphy**. On the other hand, the opposing character state, inherited from the common ancestor (thus not transformed) and presented by the other daughter taxon, is named **plesiomorphy** (Fig. 1).

*Only apomorphic character states provide necessary and sufficient evidence to identify a natural (monophyletic) group.* They are the only traits that identify a change in the original state of a given character, which is kept by a population after the split of a given taxon and, therefore, indicate the occurrence of cladogenesis. The sharing of plesiomorphic character states among different taxa, on the other hand, does not provide evidence of monophyly. The presence of these characters in a given population after a splitting event may be due the inheritance of unaltered (not transformed) states from a common ancestor. Therefore, the *sharing of plesiomorphic characteristics does not delimit a natural group.*

In order to determine the genealogical relationships among taxa, several character states common to these organisms must be listed. However, these character states must vary among these taxa in a way that some, but not all taxa being studied, share a given state. The next step is to compare these states to the ones found in taxa outside the group of interest, in order to determine which represents a novelty (thus, an apomorphy), and which was inherited from the common ancestor (thus, a plesiomorphy).

Given a group of taxa expressing two different character states, only the sharing of apomorphic states indicates a shared evolutionary path of a subpart of this group. For example, among actinopterygian (ray-finned fishes), eye of Pleuronectiformes (flatfishes, flounders, soles, and halibuts) migrates ontogenetically from one side of the head to the other. Accordingly, eye asymmetry is an exclusive characteristic of adult Pleuronectiformes. In contrast, all other actinopterygians retain eye symmetry in adults. Since eye symmetry is also present in all lineages of ► [Vertebrates \(Chordata\)](#), it is recognized as the **plesiomorphic state**. In this context, eye symmetry is a shared plesiomorphy (**symplesiomorphy**), and cannot be used to delimit ► [“Actinopterygii \(Bony Fish\)”](#) as a monophyletic group. On the other hand, the presence of a migrated eye in adults is the *transformed condition*, putatively present in the common ancestor of Pleuronectiformes and shared among all flatfishes. This is a shared apomorphy (**synapomorphy**) that can be used to delimit a monophyletic group encompassing all flatfishes, the Pleuronectiformes.

However, a particular plesiomorphic character state can, and will, correspond to an apomorphic, informative character state at a higher level of inclusion. For example, since the presence of a vertebral column is common to all vertebrates, it cannot be used to delimit one of its subgroups (like Gnathostomata) because it is a symplesiomorphy of gnathostomes in the phylogeny of Vertebrata. However, the presence of a vertebral column in all vertebrates, and of its absence on the other groups of Chordata, indicates that this is a synapomorphy of Vertebrata in the Chordata phylogeny.

As noted above, symplesiomorphies offer no evidence for the recognition of monophyletic groups, as they represent an unchanged, inherited character state. However, there is a second set of character states that do not add information during the reconstruction of the evolutionary hierarchy among taxa, **autapomorphies**. These are modified characteristics (apomorphies) that are unique to a single taxon. For example, when considering the interrelationship among the extant great apes (group that includes orangutans, gorillas, chimpanzees, and humans), bipedalism would be an exclusive characteristic of *Homo sapiens*. This

trait distinguishes humans from other ► **primates** rather than indicating their relationship to the remaining apes, and therefore it does not provide information about the hierarchical relationships among humans and the remaining primates (*i.e.*, which of the other primates' lineages are more closely related to the humans).

Finally, what determines if a particular character state is apomorphic or plesiomorphic is its comparison with the condition observed at the root of the cladogram. When a phylogenetic tree is obtained through a congruence analysis, the root is a taxon included in the phylogenetic analysis to represent the character states presented outside the group of interest (*i.e.*, the root would carry unaltered conditions for the characters). In the example focusing on the relationships among great apes, a good choice for a root would be the primate that is most similar to the great apes, but still not considered one of them, which in this case is the gibbon.

The root (the gibbon) should bear the unaltered conditions for some characters, meanwhile the ingroup (great apes) present new conditions. What is displayed by the gibbon will then indicate the *direction of transformation of each character, from one state to the other*. In the case of bipedalism, comparing the character state

found in the gibbon (absence) with the one found in great apes (presence) indicates that a non-bipedal primate started walking on two feet. Therefore, any character states of the ingroup (great apes) that differ from the gibbon (the root) are considered apomorphies. In other words, the root *polarizes the character states*, and enables the identification of character states as apomorphic or plesiomorphic. The root might even help (despite not being required) in the recognition of convergences among different groups (*i.e.*, similarities that are not the result of common ancestry).

### Monophyletic Versus Merophyletic Groups

As mentioned above, only apomorphic characteristics can be used to infer natural (**monophyletic**) groups. However, there are also groups of species that are not monophyletic. **Merophyletic** (or partial groups, *sensu* Bernardi 1981) is a term indiscriminately used to refer to nonmonophyletic taxa, including both **paraphyletic** and **polyphyletic** groups. **Paraphyletic** refer to groups of taxa based on shared plesiomorphies, and **polyphyletic** describe groups of taxa based on

**Monophyletic, Fig. 2** Hominoidea cladogram highlighting: (a) **monophyletic groups**, which include an ancestor and all its descendants (Chimpanzee + Bonobo in light gray; Gorilla + Chimpanzee + Bonobo + Human in dark gray); (b) **paraphyletic groups** (in light gray, grouping Gorilla, Chimpanzee, and Bonobo but excluding Human;

in dark gray grouping Gibbon and Orangutan but excluding remaining Hominoidea); (c) **polyphyletic groups** (in light gray a group formed by Gorilla and Human, and in dark gray a group containing Bonobo and Human. Both groups exclude remaining Hominoidea)

convergences (Hennig 1966). Both paraphyletic and polyphyletic groups are artificial, and distinguished from monophyletic ones by not having a natural history, thus not possessing either reality or individuality (Hennig 1966).

Another useful way to think about paraphyletic and polyphyletic groups is as follows: a paraphyletic group corresponds to a monophyletic group after the withdrawal of one or more monophyletic subgroups; and a polyphyletic group corresponds to a monophyletic group after the withdrawal of a paraphyletic subgroup (Fig. 2) (Nelson 1971; Bernardi 1981). For both groups, the resultant cladogram does not correspond to one ancestor and all its descendants (otherwise, it would be monophyletic). This second definition allows us to distinguish monophyletic and non-monophyletic groups without reference to any real characters, but conditional on a specified phylogeny (Farris 1974).

Merophyletic groups have no place in the phylogenetic system, since they are not natural groupings and do not satisfy the condition of exclusive common ancestry. However, they are still frequently used in textbooks and classrooms, since their names are traditional and can help us retrieve information. For example, the term “fishes” (Pisces, in the Latin name) corresponds to a paraphyletic group, which includes all Vertebrata except the monophyletic group of tetrapods. Therefore, in order for “Pisces” to be a monophyletic group, it would have to also encompass the Tetrapoda and thus all vertebrates would be “Pisces.” Although “fishes” retain several plesiomorphic conditions when compared to tetrapods, the use of this traditional name helps us to recover several characteristics (anatomical, physiological, behavioral, etc.) common to most of its taxa. Therefore, in order to keep the traditional name, but also provide an indication that we are aware that the group is not monophyletic, we write the name between quotes, as done above.

## Introduction

Monotremes are a unique group of mammals confined to Australia and New Guinea. The lineage leading to modern monotremes probably diverged from that leading to therians (modern placental and marsupial mammals) as much as 220 million years ago (Yu et al. 2012), so there has been abundant time for independent evolution of sensory systems and the brain. Modern monotremes cannot be considered primitive or relict, and they are certainly not models for the ancestors of placental mammals. Monotremes have undergone just as long a period of evolution as have therians. Furthermore, although they do exhibit some primitive characteristics, living monotremes are also highly specialized animals with some remarkably advanced neural adaptations (e.g., electroreception and isocortical expansion). Like all mammals (including humans), they are therefore the result of mosaic evolution, where primitive and derived characteristics co-exist in the one species.

## What Are Monotremes?

Monotremes are egg-laying mammals and are represented in the modern world by the platypus of eastern and southern Australia (*Ornithorhynchus anatinus*, of the Ornithorhynchidae) and the echidnas (*Tachyglossus aculeatus* – the short-beaked echidna of Australia and New Guinea; several species of long-beaked echidna from New Guinea – *Zaglossus bartoni*, *Zaglossus bruijni* and *Zaglossus attenboroughi*; all within the Tachyglossidae). The platypus and long-beaked echidnas are rather confined geographically, but short-beaked echidnas occupy a strikingly diverse range of habitats across the entire continent of Australia and parts of New Guinea. Monotremes lay soft, leathery-shelled eggs about 12–18 mm in length, from which the embryonic young hatch, in contrast to therian mammals that bear live young. Dependence on the mother is prolonged in all monotremes, with lactation continuing up to 140 days post-

hatching in the platypus and 200 days in the short-beaked echidna.

One might say that monotremes have always been Australian (or at least Gondwanan), because monotreme fossils are confined to the Early Cretaceous and Cenozoic of Australia (Oligocene to Recent), the Pleistocene-Holocene of New Guinea, and the early Paleocene of Patagonia, Argentina. The fossil record for Ornithorhynchidae is better than that for Tachyglossidae, probably due to the different habitats of the two groups (aquatic vs. desert/scrub/open woodland) and hence dissimilar opportunities for fossilization.

Monotremes have normal body temperatures of 30–32 °C, generally lower metabolic rates than therians, and live long lives for their body size. The platypus can be very active when hunting in cold water, so its metabolic rate approaches that of therians of the same body size. On the other hand, the short-beaked echidna exhibits a lower level of activity than the platypus and is able to use torpor and hibernation to reduce energy expenditure even further during cold months, but there is no evidence that long-beaked echidnas or the platypus employ torpor (Nicol et al. 2008).

## Monotreme Electroreception

Electroreception is a useful sense for aquatic animals living in murky water and it has evolved independently several times among vertebrates. It evolved probably once in agnathids, twice in teleosts, once in non-teleosts, and either once or twice in amphibians (Butler and Hodos 2005).

Monotremes are most famous for being the only mammals with electroreception, although this sense should be considered a complement to somatosensation in the platypus, and to somatosensation and olfaction in the echidnas. Indeed, electroreception on its own would be unlikely to provide sufficient information for prey detection in either the platypus or echidnas, because of sensitivity problems. The electro-sensory apparatus is the bill of the platypus (both upper and lower) and the snout tip in the short- and long-beaked echidnas.

Electroreceptive function is confined to the trigeminal pathway in all monotremes. This pathway is particularly striking in the platypus, where it is estimated that 1,344,000 myelinated axons of the trigeminal nerve supply the upper and lower bill (Manger and Pettigrew 1996). Approximately half of those innervate the putative electroreceptors (see below), while the rest innervate mechanoreceptors of the bill. The trigeminal nerves of the echidnas are much smaller (only 7% of the area of the platypus nerve).

The electroreceptors in the platypus are of the ampullary type, meaning that they are open to the skin surface through a fluid-filled duct and respond to low-frequency electrical rhythms, such as are produced by the regular muscle contractions or tail flicks of prey animals (0.1–50 Hz). Electroreception in the platypus is most closely associated with the mucous sensory glands of the upper and lower bill, estimated at 30,000 to 40,000. When viewed from the bill surface, these glands have a peony blossom-like appearance due to the presence of many epithelial “flakes” surrounding the duct pore (Andres and von Düring 1988). The duct provides a low resistance pathway for electrical fields to reach the sensory nerve endings at the papillary part of the gland (Iggo et al. 1988). In contrast to non-mammalian electroreceptors, the electrosensory terminals of the mucous sensory glands of the platypus are naked and do not contact a sensory cell (Manger and Pettigrew 1996). This may account for the short latency of electroreceptor activation in the platypus (0.8 ms) compared to ampullary electroreceptors of fish (see discussion in Gregory et al. 1989).

The mucous sensory glands are arranged in parasagittal stripes along the external surfaces of the upper and lower bill (Andres and von Düring 1988). The platypus sweeps its bill through the water from side to side when hunting, so these stripes may act as an antenna, detecting the movement of electrical field lines across the stripe (Manger and Pettigrew 1996).

The platypus spends a significant portion of the day out of the water, so a mechanism is needed to prevent fluid loss from the ducts of the mucous sensory glands. The pores of mucous sensory

glands open when the bill is exposed to cold water and close when exposed to dry air, protecting the duct contents from drying. This reflex is stimulated by exposure to cold and mediated by sympathetic nerve fibers to the gland.

The echidnas also have putative electroreceptors in their snout tips, but these are far fewer in number than the platypus. The short-beaked echidna has only a few hundred and the long-beaked echidna about 3,000 sensory glands (Manger et al. 1997). Much like in the platypus, the sensory apparatus is associated with an elongated dermal mucous gland of about 0.3 mm diameter (Manger and Hughes 1992). Axons innervate the modified epidermal portion of the gland to form a sensory cuff. In the real world, the snout is used as a push probe, thrust into loose soil, or leaf litter in search of invertebrates.

## Monotreme Somatosensation

Somatosensation, principally the detection of mechanical and thermal stimuli at the skin surface, may be just as behaviorally important as electroreception for the monotremes and models of real-world behavioral use of electroreception require integration of electro- and mechanosensory input at the cortical level.

Monotreme bills and snouts have highly specialized sense organs called push-rod mechanoreceptors. In the platypus, this consists of a mobile epidermal rod of stratified keratinocytes, about 400  $\mu\text{m}$  long and 70  $\mu\text{m}$  wide. When the complex is viewed from above, the rod tip looks like a dome bulging from the epidermal surface and surrounded by rings of flattened keratinocytes (Andres and von Düring 1988; Manger and Pettigrew 1996). Three types of mechanosensory assemblies are located within the rod itself (central vesicle chain, peripheral vesicle chain, and Merkel cells), and a further three to six Paciniform corpuscles are located in the dermis immediately deep to each rod. Collectively, these give the platypus bill a suite of slowly and rapidly adapting mechanoreceptors to detect both sustained and vibratory indentation of the bill surface. Push-rod mechanoreceptors are scattered

across all four surfaces of the bill, but concentrated at the lateral and rostral borders (Andres and von Düring 1988; Manger and Pettigrew 1996).

In the short-beaked echidna, the most sensitive part of the beak is the distal 1–2 cm. Mechanoreceptors in the echidna beak include: free nerve terminals; lamellated receptors; intra-epidermal discoid, vesicle chain, and cluster receptors; and Merkel cell receptors (Andres et al. 1991; Manger and Hughes 1992). The push-rod organ of the echidna is shorter than in the platypus. More significantly, the push-rod of the echidna is linked to surrounding epidermal cells by desmosomal junctions, so its mobility and sensitivity to shearing movement are greatly limited compared to the platypus (Manger and Hughes 1992).

### Integration of Electoreception and Somatosensation in the Cerebral Cortex

How do electro- and mechanoreception work together in the real world? The mechanics are undoubtedly different in the platypus and the echidnas as reflected in bill and beak shape. The platypus bill is a large flat electrical antenna and mechanosensory device to be swept from side to side while swimming, whereas the beaks of the echidnas act more as push probes.

Each individual sensory channel of the platypus bill is of limited sensitivity, so there must be significant spatial and temporal summation to achieve a behaviorally useful input. Captive platypuses engage in a continuous sweeping of the bill from side to side at about 75 cycles per min. This appears to be important in locating the direction of an electrical target by reorientating the head relative to the source, perhaps to present the more sensitive part of the bill towards the stimulus (Proske et al. 1998) or to sample electrical field-lines sweeping across the bill. When a captive platypus is exposed to a novel electrical stimulus, it produces automatic head movements towards the source and snaps at the electrode (Manger and Pettigrew 1995), even when the source is inedible. These studies suggest that there are both voluntary and reflexive elements in the alignment of the platypus to electrical sources.

Electro- and mechanosensation most probably work in concert to detect both the direction and distance of the prey. Although the electrophysiology of these central pathways is poorly understood, it has been suggested that a comparator system functions within the enlarged primary somatosensory cortex of the platypus (Fig. 1). Electrical signals propagate through the environment at the speed of light, whereas the pressure waves detected by the mechanoreceptors are substantially slower. For example, the tail flick of a prey crustacean at a distance of 15 cm from the bill would generate a mechanical disturbance in the water that is delayed by approximately 10 ms after the electrical signal (Pettigrew et al. 1998). A neural system that is sensitive to the delay between the electrical and mechanical stimulus could be used to assess range to prey. Pettigrew and colleagues have suggested that activation of cortical bimodal neurons that facilitate optimally at a variety of different time delays between electrical and mechanical signals could provide such a system (Pettigrew et al. 1998), but this has never been tested experimentally.

### Monotreme Olfaction

No behavioral or physiological studies of olfaction have been carried out in captive monotremes, but several observations indicate the behavioral importance of this sense in tachyglossids. During the mating season, usually solitary echidnas gather to form trains of males following females, suggesting that olfactory signals are critically important for finding mates and assessing reproductive status of conspecifics. Behavioral observations of wild short-beaked echidna also suggest that olfaction plays an important role in detecting ants, termites, and other invertebrates.

The two living groups of monotremes have very different olfactory capacities, and this is reflected in the very different structure of their olfactory systems. The poorly osmotic, semi-aquatic platypus has a greatly reduced main olfactory system but a surprisingly large

**Monotreme Sensory Systems, Fig. 1** Somatosensory system structures as seen in frontal sections through the brain of a juvenile platypus (240 mm body length). Note the extensive somatosensory regions in the cerebral cortex (**a**, **b**; PV – parietoventral somatosensory area, R – rostral somatosensory area, S1 – primary somatosensory area; names in parentheses indicate body regions represented here). The electrosensory areas are located in S1. The somatosensory nucleus of the dorsal thalamus (VPM – ventral posteromedial thalamic nucleus), concerned with mechano- and electroreception from

the bill, is also very large (**a**), as are the trigeminal sensory nuclei in the brainstem (**b**; Pr5mc – magnocellular part of principal trigeminal sensory nucleus, Pr5pc – parvocellular part of principal trigeminal sensory nucleus; Sp50 – oralis part of spinal trigeminal sensory nucleus). Amg – amygdala; Au – primary auditory cortex; Hi – hippocampal formation; Pu – putamen; RSG – retrosplenial gyrus; V – primary visual cortex. The line diagram shows the position of the two sections (**a**, **b**) in the extent of the brain from olfactory bulb (OB) in the front to cerebellum (Cb) in the rear. Scale bar in (**a**) applies to both photomicrographs

M

collection of vomeronasal chemoreceptor genes, as great as any placental mammal studied so far. This suggests that although the main olfactory pathways of the platypus are unlikely to make a significant contribution to prey detection, the accessory or vomeronasal olfactory system may be very important in courtship and recognition of offspring (Griffiths 1978). On the other hand, the long- and short-beaked echidnas both have highly specialized main olfactory systems, although very little is currently known about olfactory receptor genes in the echidnas. The main olfactory system in both types of echidna shows signs of convergence with myrmecophagous xenarthrans and

probably acts as an important sensory complement to the electrical organs of the snout tip.

The nasal cavity of the platypus is relatively simple in structure, with tiny nasal and ethmoidal turbinates (Griffiths 1978), but the vomeronasal organ is large, with a pair of pouches that open into the front of the nasal cavity, rather than the nasal cavity. By contrast, the nasal cavities of both long- and short-beaked echidnas are structurally complex, with seven endoturbinates suspended vertically from the ethmoid, many ectoturbinates, and groups of naso- and maxilloturbinates. The cribriform plate of the short-beaked echidna is approximately 300 mm<sup>2</sup> in area and reaches 440 mm<sup>2</sup> in *Z. bartoni* (*diamondi*).

Olfactory receptor genes (main olfactory pathway – OR, TAAR; vomeronasal pathway – V1R and V2R families) have been studied in the platypus, but not the echidnas. The platypus has only a few intact OR and TAAR genes (261 and 4, respectively), compared to 1037 and 15 in the laboratory mouse (Niimura and Nei 2007). By contrast, the vomeronasal pathway genes are abundant in the platypus. The V1R family detects odorants in the air, whereas V2R detect chemicals in water. Despite its poor main olfactory system ability, the platypus V1R family has 270 intact genes and 579 pseudogenes; and the V2R has 15 intact genes, 55 potentially intact genes, and 57 pseudogenes (Grus et al. 2007).

The main olfactory bulb, anterior olfactory area, olfactory tubercle, and piriform cortex are all quite small in the platypus, although the accessory olfactory bulb is of substantial size (Ashwell 2006). By contrast, the main olfactory bulb of both short- and long-beaked echidnas is large and folded, presumably to increase the available surface area for synaptic input to glomeruli. The short-beaked echidna has a complex piriform cortex, with regional differences of cellular structure and chemical architecture around the circumference of the large piriform lobe (Ashwell and Phillips 2006).

The function of the large frontal cortex that lies rostral to the primary motor cortex of the echidnas has always been a mystery. Divac and colleagues (Divac et al. 1987) showed that the frontal cortex of the short-beaked echidna receives abundant input from the piriform cortex, medial, and cortical (olfactory) parts of the amygdala, and the medial and lateral entorhinal cortex. This pattern of input suggests that the expanded frontal cortex receives a rich source of olfactory input, as would be anticipated if it were serving as a chemical sense integration center.

## Monotreme Audition

The middle and inner ear of monotremes show some remarkable differences from therian mammals, but these are of an underived nature, indicating that hearing is poorly developed in the

group. In fact, hearing is unlikely to be of major behavioral importance in the semiaquatic platypus, although it may be important for the echidnas in detecting invertebrates. In both the tachyglossids and the platypus, hearing is optimal around the relatively low frequency of 4–5 Hz. Hearing among echidnas may actually be best for bone conduction, consistent with the use of their long, pointed snouts as push probes for detecting low-frequency vibrations produced by invertebrates in the soil.

Middle ear structure in monotremes suggests relatively poor functional capacity of the auditory system. The tympanic membrane of the short-beaked echidna is supported by a hook-shaped tympanic bone and is relatively loosely supported, but the malleus and incus are rather tightly bound to the periotic bone (Aitkin and Johnstone 1972) and do not move freely. Unlike many placental mammals, where the stapes is stirrup-shaped, the stapes in monotremes is a columnar bone expanded distally to cover the oval window, which is actually round in these mammals. Mechanical amplification across the auditory ossicle chain is probably poor.

The monotreme inner ear is like other mammals, in that there are distinct inner and outer hair cells in the organ of Corti (Griffiths 1978). However, the cochlea is shorter than therians of a similar body weight and is only loosely coiled in the monotremes, achieving a curvature of only 130 to 180° (Gray 1908; Fox and Meng 1997) in contrast to the 720° or more found in therians. The total number of inner hair cells is similar in the monotremes and therians, but the outer hair cells (which engage in the cochlear amplifier mechanism) appear to be fewer (Ladhams and Pickles 1996). There is also an unusual structure known as the macula lagena (a distinct sensory area at the end of the cochlear duct and separated from the organ of Corti) present in both the platypus and short-beaked echidna (Ladhams and Pickles 1996). Its role is unclear, but it shows some structural features (i.e., opposing stereocilia polarity) that are similar to the vestibular sense organs.

The area of the primary auditory cortex is relatively small in both the platypus and short-

beaked echidna (Krubitzer et al. 1995), consistent with less behavioral reliance on auditory function compared to other senses.

## Monotreme Vision

Vision is not a major sense used by monotremes and visual acuity of monotremes is poor. Behavioral studies of the short-beaked echidna by Gates (1978) showed that discrimination of vertical from horizontal lines is possible only at a line width greater than  $0.499^\circ$ , comparable to that in rodents. Nevertheless, there are some interesting aspects of monotreme vision related to cone photoreceptor evolution.

All the monotremes are adapted to a crepuscular lifestyle, with retinas that are dominated by rod photoreceptors, with cones making up only 10% even in central retina. Some distinctive features of the monotreme eye include cartilage reinforcement of the sclera, double cone photoreceptors, and the presence of oil droplets in the cone photoreceptors (at least in the platypus) (Zeiss et al. 2011). The distributions of photoreceptors and retinal ganglion cells across the retina of the short-beaked echidna are relatively flat (i.e., minimally concentrated), meaning that there is only poor development of a zone for higher acuity vision.

All monotremes are dichromats. This means that they determine colors by comparing the input from two types of cone photoreceptors. In the platypus, the peaks of the SWS2 and LWS pigments of the platypus cone photoreceptors are at 451 nm and 550 nm, respectively. The peak for the LWS pigment of 550 nm is similar to that found in many marsupial and placental mammals for their LWS pigments. The peak at 452 nm for SWS2 is at only a slightly longer wavelength than the violet-sensitive SWS1 pigments of some placental mammals (Hunt et al. 2007). The *SWS1* opsin gene found in therians may have been deleted during monotreme evolution (Wakefield et al. 2008).

All monotremes have poor binocular vision, because there is minimal overlap of the visual fields of the two eyes, and 99% of retinal ganglion

cell axons cross at the optic chiasm (Campbell and Hayhow 1971, 1972). Nevertheless, there is good interhemispheric transfer of information through the large anterior commissure. The retinorecipient nuclei of the thalamus are unusual in monotremes, in that the pregeniculate of the prethalamus is widely separated from the lateral geniculate nucleus of the true thalamus (Campbell and Hayhow 1971, 1972).

The visual cortex is small in both the platypus and short-beaked echidna. Krubitzer (1998) identified at least two visual field representations in the cortex of the platypus (caudal and rostral). The caudal visual field representation may be homologous to primary visual cortex of therians but is so unspecialized that visual field magnification on the platypus visual cortex (0.03 mm per degree; Pettigrew et al. 1998) is no better than the tiny laboratory mouse. It may be that the midbrain is a much more important visual processing center in the platypus than the visual cortex. Krubitzer also reported that there are two visual field representations in the short-beaked echidna (Krubitzer 1998), but the physiological evidence for this is not well-documented.

## Conclusions

Although monotreme electroreception has received the most scientific attention, somatosensation and olfaction are also very important behaviorally for the group and there is evidence of striking cortical adaptation for those senses in the platypus and echidnas. Monotremes should therefore not be seen as primitive or relict mammals, because they are clearly successful mammals with advanced nervous systems with derived characters. Although the platypus is clearly a trigeminal somato- and electrosensory specialist, the olfactory centers of the echidnas are large, complex, and laminated, much like that seen in other myrmecophagous mammals. The large frontal cortex of the echidnas may act as a chemosensory integration center and store detailed information about home range topography.

## Monty Hall Dilemma

Michael R. W. Dawson

Department of Psychology, University of Alberta,  
Edmonton, AB, Canada

### Synonyms

Monty hall problem; Three box problem; Three Prisoners Problem

### Introduction

Beginning in 1963, contestants on the American television program *Let's Make A Deal* competed to win prizes. In one game, a contestant was confronted with three closed doors. One of these doors concealed a prize (such as an automobile), while the other two doors did not (they often

concealed a goat). The contestant began by picking one of the three doors, which remained unopened, in the hope that it concealed the prize. Then the host of the program, Monty Hall, opened one of the other doors to reveal a goat. To end the game, the contestant had to finally decide whether to stay with their original choice or instead to switch their choice to the remaining unopened door. After the contestant decided to “stay or switch,” the location of the prize was revealed.

Why might this game be of interest to comparative psychology? One reason is that when human participants are presented with the standard version of this task (described in more detail below), they perform very poorly on it. Generally speaking, people believe that after the host reveals the goat behind the door, there is a 50–50 chance that the prize is hidden by the door that was originally selected and (for a variety of reasons) are likely to stay with their original choice. However, this belief is false: it can be shown in a variety of ways that a contestant is twice as likely to win the prize by switching their choice to the other door (Rosenhouse 2009). A second reason is that some animals may outperform humans on this task. For instance, some studies have shown that pigeons quickly learn to always switch their choice in order to maximize reward (Herbranson and Schroeder 2010), which is the optimal strategy (Stephens and Krebs 1986).

This article introduces the Monty Hall dilemma and its psychological implications. It begins by considering the properties of the standard version of this task. It describes variations of this standard version and how these variations can be used to study the processes used to play the game. It also briefly reviews some of the psychological studies of the Monty Hall problem as well as the implications of this research.

### The Standard Monty Hall Dilemma

The Monty Hall dilemma is a mathematical brain teaser because while mathematics proves that switching from the initial choice actually doubles the probability of winning, human intuition strongly indicates that switching door choice

should not affect the likelihood of winning. Importantly, the proof that switching from the initial choice doubles the likelihood of winning requires that the game have particular characteristics which define its standard version (Rosenhouse 2009).

The standard version of the Monty Hall dilemma requires that the probability that the prize could be behind any of the three doors is equal. It also requires that the host never opens the door selected by the contestant and never opens the door that conceals the prize. Finally, if the contestant's first pick is the door that hides the prize, the standard version requires that the host randomly choose which of the two remaining doors to open. Of course, if the contestant's first pick is a door that hides a goat, then the host is forced to open the other door that does not conceal the prize.

If the characteristics of the game conform to those of the standard version described above, then the optimal strategy for winning is to switch choices. Informally, one can argue for this strategy by noting that when the contestant makes their first choice, they have a one in three chance of being correct. This means that there is a two in three chance of the prize being behind a door that the contestant did *not* choose. This is not changed when the host opens a losing door. In other words, after the losing door is opened, there is still a one in three chance of success with the original choice, but the likelihood that the prize is behind the other unopened door is now two in three, because it is the only remaining member of the set that had a 2/3 probability of concealing the prize.

The Monty Hall dilemma is challenging because this informal account of the situation runs counter to strong (and incorrect) intuitions (Piattelli-Palmarini 1994). When the host reveals a losing door, the contestant is faced with two closed doors, one of which hides the prize. Intuition strongly suggests that each remaining door must be equally likely to be the winner. However, this intuition fails to realize that the host's choice is constrained by the contestant's first choice: if this first choice is of a losing door, then the host is forced to open the other losing door. This makes the dilemma one based on conditional

probabilities, which means that the only door whose probability of winning changes is the door not picked by either the contestant or the host.

There are a number of formal methods that can be used to prove that switching is the best strategy for winning the standard version of the game (Rosenhouse 2009). One approach is to simply enumerate all of the possible ways that the game can proceed. An examination of the resulting table of possibilities quickly indicates that the probability of winning by staying is 1/3 while the probability of winning by switching is 2/3 (Selvin 1975). Another approach is to use Bayes' theorem to use equations involving conditional probabilities (Krauss and Wang 2003). A third approach is to run Monte Carlo simulations, which again quickly demonstrate the underlying probability structure of the task as well as the advantage of switching from the initial choice.

The Monty Hall problem is particularly interesting because human intuitions about the puzzle prevent its mathematical solution from being readily accepted. As a result, this problem is one of the best examples of a mathematical brainteaser and was originally presented as such in the 1950s by Martin Gardner as the "Three Prisoners Problem" (Gardner 1959a, b). When the Monty Hall dilemma was reintroduced to the public in *Parade Magazine* in 1990, it caused thousands of readers – many of whom were professional mathematicians – to write letters that challenged the (correct) solution of the problem that had been provided by columnist Marilyn vos Savant (1990a, b, 1991). Indeed, famed mathematician Paul Erdos was extremely reluctant to accept the correct solution to the dilemma because it ran counter to his intuitions (Rosenhouse 2009). The formal logic of the Monty Hall dilemma is so difficult to accept that Massimo Piattelli-Palmarini uses it as his "grand finale" example of cognitive illusions (Piattelli-Palmarini 1994).

## The Psychology of the Monty Hall Dilemma

The skepticism held by professional mathematicians concerning the correct solution to the Monty

Hall dilemma is further reflected and magnified in the performance of average human participants on this task. A wide variety of studies show that people have a strong preference to stay with their original choice in the standard version of the task.

Consider one illustrative study (Granberg and Brown 1995) that presented a written description of the standard version of the dilemma to introductory sociology students. After laying out the basic nature of the problem, the description told participants that they had initially selected Door 1 and had then been shown a goat behind Door 3. Given this information, they were then simply asked to decide between staying with Door 1 (the non-optimal decision) and switching their choice to Door 2 (the optimal decision). In this study, only 13% of the participants indicated that they would switch their choice. A follow-up study employed a similar method to compare performance from participants from different cultures (Brazil, China, Sweden, the United States) (Granberg 1999a). On average, only 17% of the participants switched their choice, and there were no statistical differences between the performances of participants from different countries. In general, the psychological literature suggests that only between 9% and 21% of human participants in a typical Monty Hall experiment will decide to switch from their original choice (Mazur and Kahlbaugh 2012).

The typical behavior of human participants on the Monty Hall dilemma is so well established that psychologists now focus on explaining its irrationality. Why do people stay with their original choice when switching would double their probability of winning? A variety of explanations have been proposed.

Social psychologists have suggested that regrettable actions have more impact than do regrettable inactions; as a result participants will feel better about the Monty Hall dilemma if they lose after staying than they would if they lost after switching (Gilovich et al. 1995; Granberg and Brown 1995). A related theory is to appeal to what is known as the endowment effect, which is the hypothesis that people assign more value to objects merely because they own them (Thaler

1980). In the context of the Monty Hall dilemma, the endowment effect predicts that participants assign a higher value to the door they choose first choice more merely because it has been chosen and is therefore less likely to switch away from it.

Cognitive psychologists argue that the poor performance on the Monty Hall dilemma reveals poor probabilistic reasoning (James et al. 2018; Shimojo and Ichikawa 1989; Tubau et al. 2015). This position is consistent with other studies that show that human performance improves if information about the problem is presented in terms of frequencies instead of probabilities or if more detailed feedback about behavior is provided (Krauss and Wang 2003; Saenen et al. 2015).

## Variations of the Monty Hall Dilemma

Psychologists are interested in the Monty Hall dilemma because it can be easily presented to participants, it produces a robust and counterintuitive effect, and it stimulates a wide-ranging discussion about why humans have problems with this task. A second reason for psychology's interest is that the task can be easily manipulated in order to alter the optimal approach to dealing with the dilemma. This means that psychologists can explore numerous variations of the dilemma in order to attain better understanding of how participants approach it.

Many of the possible variants of the problem, and their mathematical implications, are discussed in detail by Rosenhouse (2009). For instance, one simple variant assumes that the host is unreliable because they randomly choose the door to reveal after the contestant has picked first. This means that sometimes the host will open the door that conceals the prize, which abruptly ends the game. In this variant, there is no advantage to switching if the host opens a door that reveals the prize. This is because the host's choice is random, and therefore not constrained by the contestant's selection. This means that the prize is equally likely to be behind the two remaining unopened doors.

Another simple variation of the dilemma is to use more than three doors. In general, assume that

there are  $N$  doors in the game, where  $N \geq 3$ . As in the standard version of the game, the contestant chooses one of the doors, which has a  $1/N$  probability of concealing the prize (as do the others). The host then opens  $N - 2$  doors, each of which reveals a goat. It seems that the structure of this task is identical to the standard version, because once again the contestant is faced with two closed doors and must decide whether to stay or switch. However, as  $N$  increases in size, staying with the initial choice is more and more irrational. This is because the probability of winning by switching is  $1 - 1/N$ . Thus a simple way to alter the probability of reward associated with choice behavior is to increase the number of doors in the game.

Of course, a more direct approach to manipulating rewards associated with choice is to alter the probability structure of the dilemma by not requiring the doors in the game to have equal probabilities of hiding the reward. In this case, the optimal solution is to initially choose the door that has the smallest probability of concealing the prize (Granberg 1999b). Then when the host (who is assumed to know where the prize is) reveals a goat, the winning strategy is to switch.

Of course, one issue with the optimal strategy to use when the doors have unequal probabilities of hiding the prize is that the contestant does not know in advance which door has the least likelihood of being the winner. Experimental psychologists have developed a variation of the dilemma that permits this obstacle to be overcome in principle. Instead of having participants solve a single instance of the problem, one can provide multiple instances of the dilemma and have the participant solve each one in sequence. This permits the participant to receive feedback about their choices and permits them to learn about how to solve the task, for instance, by learning that one strategy is better than the other or by learning that one door is less likely to hide the prize than are the others.

To provide an example of this approach, consider one study that trained human participants on the task and which also adopted other variations of the problem by using four doors and by assigning unequal probabilities of reward to each door in one of the conditions (Granberg 1999b). Granberg

used a computer to present the dilemma to participants, who then were trained by playing the game 60 different times at their own pace. All of the participants had a strong preference to stay with their first choice at the beginning of their training – only about 9% of the 192 participants began the study by switching from their first choice. As training continued, there was a significant increase in the number of switches made by participants. However, this increase plateaued midway through training, suggesting that participants learned something as they were trained but in general did not learn the optimal strategy.

One advantage of training participants by presenting them with a number of trials of the Monty Hall dilemma is that researchers can explore the factors that affect what is learned about the task. For example, one study provided 80 trials of training and manipulated the kind of feedback that participants received (Saenen et al. 2015). The feedback was either in the form of the participant's probability of winning or in the form of the frequency of the rewards that had been received. As well, feedback could either be unconditional (i.e., participants were simply informed about their overall performance) or conditional (i.e., participants were informed about their performance when they stayed and about their performance when they switched). It was found that the participants who learned to switch the most (on approximately 85% of the last 20 trials) were those who were provided conditional feedback in frequency format. However, while choice behavior was altered by the feedback, it did not appear to alter participants' understanding of task probabilities which were also measured at the end of the study.

## The Comparative Psychology of the Monty Hall Dilemma

A second advantage of training participants by presenting them with a number of trials of the Monty Hall dilemma is that this permits human performance to be compared with the performance of other species. This is because while animals cannot be told the basic structure of the

problem, they can be trained in a fashion that mimics the constraints of the task. One reason that animal performance on the Monty Hall dilemma is of interest is because the problem is an example of foraging task in which predictions are being made about the location of rewards (Herbranson and Schroeder 2010).

The most influential comparative study of the Monty Hall dilemma studied the performance of pigeons to that of humans (Herbranson and Schroeder 2010). Pigeons were trained in an apparatus that contained three pecking keys that could be illuminated. The animals would peck one key, and then one of the two unselected keys would darken. This was analogous to the host opening a door to reveal a goat. The pigeons were then faced with two illuminated keys: the one that they had pecked originally and one other. Their choice in this situation was in essence “stay or switch.” When they were rewarded in accordance with the standard Monty Hall dilemma, they learned to switch. On the first day of the study, pigeons would only switch on about 36% of their trials. However, after 30 days of training, the pigeons would switch their choice on over 96% of the trials. In other conditions, the reward structure of the task was altered so that pigeons were rewarded for staying instead of switching. Herbranson and Schroeder found that the birds quickly learned to approximate the optimal strategy in these non-standard conditions.

Of particular note is that when Herbranson and Schroeder (2010) trained human participants in a fashion that was analogous to the pigeons, they discovered that human performance differed markedly from that of the birds. Human participants did not quickly learn to adopt the optimal strategy. For instance, in a condition that mirrored the structure of the standard Monty Hall dilemma, by the end of 100 trials of training, human participants would be expected to switch only about two thirds of the time. Thus, instead of learning the optimal strategy, their behavior suggests that they learned to match probabilities (Estes 1964), with their likelihood of staying or switching becoming roughly equal to the probability of reward associated with each of these choice behaviors. Similar results – with pigeons learning optimal strategies

but humans failing to do so – were produced in a follow-up study in which the probability of reward associated with each of the three choices was not equal (Herbranson and Wang 2014). In general, these results raise the possibility that some animals are smarter than humans when confronted with the Monty Hall dilemma.

Other pigeon studies have attempted to vary the experimental conditions in a fashion that permits the exploration of other factors that have been raised to account for human performance. For example, some have attempted to create an endowment effect in birds by requiring pigeons to peck their first choice 20 times before proceeding to the next stage of the Monty Hall dilemma (Stagner et al. 2013; Zentall et al. 2015). These experiments found no evidence of an endowment effect. However, they are also of interest because the performance of the pigeons is less optimal than that observed in other studies (Herbranson and Schroeder 2010; Herbranson and Wang 2014).

Similar results (i.e., poorer performance in animals than that described by Herbranson and Schroeder) have been reported in other studies. For example, in one experiment (Mazur and Kahlbaugh 2012), pigeons performed poorer, and humans performed better, than was found by Herbranson and Schroeder (2010). Another study found similar performance in both pigeons and rats, where both species learned to switch (Stagner and Zentall 2015). Interestingly, this study found that both species learned to perform less optimally than did the pigeons trained by Herbranson and Schroeder. An experiment that compared the performance of humans and monkeys found similar performance in each species (Klein et al. 2013). While some learning to switch was evident in both groups of participants, there was no indication that learning of an optimal strategy occurred.

In short, the comparative psychology of the Monty Hall dilemma suggests that some species of animals, in comparison to humans, may be able to better learn an approach to the task that approximates the optimal strategy. However, this evidence is incomplete, suggesting that more comparative explorations of the problem are required.

## Conclusion

In summary, the Monty Hall dilemma is a mathematical brainteaser in which participants are confronted with a choice to find a prize: stay with an initial pick or switch to the other available. In the standard version of this problem, the best strategy is to switch, which doubles the probability of winning. However, this strategy is not favored by people who have an extremely strong tendency to stay with their initial pick and who often mistakenly believe that staying and switching are equally likely to yield a reward. This less than optimal strategy is resistant to explanations about the underlying probability structure of the dilemma and is also difficult to change when participants are provided numerous trials of training on the problem. The Monty Hall dilemma is easily presented to participants, and many variations of it exist that permit its nuances to be investigated and also permit human performance on the dilemma to be compared to animals. These latter investigations suggest that some species of animals quickly learn to perform much better on this task than do humans, although this difference has not been completely confirmed. In short, the Monty Hall dilemma appears to provide a flexible experimental medium that can be used to explore issues that include the social psychology of regret, Bayesian reasoning, probability learning, and optimal foraging strategies.

## Introduction

“Perhaps the most quoted statement in the history of comparative psychology is Lloyd Morgan’s canon” (Dewsbury 1984, p. 187). “To this it can be added that perhaps the most misrepresented statement in the history of comparative psychology is Lloyd Morgan’s canon” (Thomas 1998, p. 158). Conwy Lloyd Morgan (1852–1936) did not refer to it as a “canon” but as a “principle.” However, it quickly became known as “Morgan’s canon,” and that is how it will be identified here, unless Morgan is being quoted. Morgan’s canon was intended to guide choice among alternative explanations of animal behavior. This entry emphasizes at least 12 decades of misrepresentation of Morgan’s canon as a guide and provides fundamental guidelines for constructing the best explanations in animal cognition and psychological science.

## Morgan's Canon

The most cited version of Morgan’s canon is in his *Introduction to Comparative Psychology* (Morgan 1894, p. 53):

In no case may we interpret an action as the outcome of the exercise of a higher psychical faculty, if it can be interpreted as the outcome of the exercise of one which stands lower in the psychological scale.

Realizing early misunderstanding of the canon, Morgan (1903, p. 59) refined it as follows:

In no case is an animal activity to be interpreted in terms of higher psychological processes, if it can be fairly interpreted in terms of processes which stand lower in the scale of psychological evolution and development.

### Misrepresentations of Morgan's Canon

The most frequent misrepresentation of Morgan's canon occurred as early as 1896 when Stanley equated it with Sir William Hamilton's (1788–1856) "law of parsimony." In turn, Hamilton had equated parsimony with William of Ockham's (c. 1285–1349) "razor." Generally, Morgan's canon, Hamilton's law of parsimony, and Ockham's razor, often incorrectly, have been interpreted as advocating that when two or more explanations are available to explain natural phenomena (including animal behavior), one should choose the simplest (see Thomas, 1998, 2001, 2007 and the references contained within).

The second most frequent misrepresentation is that Morgan's canon opposed anthropomorphism, and the third most frequent is that it opposed the use of anecdotes to describe and explain animal behavior. Morgan's alleged opposition to anthropomorphism and using anecdotes as evidence for animal intelligence typically were linked erroneously to George John Romanes (1848–1894) and his book, *Animal Intelligence* (1882).

### Ockham's Razor

The main point to be made about Ockham's (also known as Occam's) razor is that Ockham meant it to be only a methodological stricture for choosing among alternative logical formulations; that is, he did not intend that it be applied to natural phenomena. Interestingly, scholars (Moody 1967 and others) have not located among Ockham's writings its most frequently cited version, "*Entia non sunt multiplicanda necessitate*" (Entities are not to be multiplied without necessity). However, comparable strictures have been found among Ockham's writings, such as "What can be done with fewer [assumptions] is done in vain with more." (Moody's translations). To conclude this brief account of Ockham's razor, it would be remiss to (a) fail to note that Ockham never referred to his stricture as a "razor" or (b) fail to

recognize that Ockham was not the first to suggest such a stricture. Aristotle, and others between Aristotle and Ockham, proposed similar strictures. Aristotle intended that his stricture be used to choose among explanations of natural phenomena.

### Hamilton's Law of Parsimony

Sir William Hamilton equated the law of parsimony with Ockham's razor as follows:

Without descending to details. . .there exists a primary presumption of philosophy. This is the law of parsimony; which prohibits without a proven necessity, the multiplication of entities, powers, principles or causes; above all the postulation of an unknown force where a known impotence can account for the phenomenon. We are therefore entitled to apply "Occam's razor" to this theory of causality, unless it be proved to explain the causal judgment at a cheaper rate. . . (Hamilton 1855, p. 580)

Pearson (1892) explained that Hamilton also extended the law of parsimony to natural phenomena. Pearson first reported that Hamilton added some scholastic axioms that were valuable as canons for economy of thought.

When, however, Sir William Hamilton adds to them, *Natura horret superfluum*, and says that they only embody Aristotle's and Newton's dicta that God and Nature never operate superfluously and always through one rather than a plurality of causes, then it seems to me we are passing from the safe field of scientific thought to a region thickly strewn with the pitfalls of metaphysical dogma. (p. 482)

### Morgan's View of Simplicity

As noted above, Ockham's razor, Hamilton's law of parsimony, and Morgan's canon in general use have in common the assumption that the simplest explanation (e.g., of an animal's behavior) is preferable. However, Morgan (1894) explicitly disavowed that assumption. Immediately after stating the canon on page 53, Morgan began anticipating some objections that might be raised against it. On page 54 Morgan wrote:

A second [anticipated] objection is that by adopting the principle in question, we may be shutting our eyes to the simplest explanation of the

phenomena. . . But surely the simplicity of an explanation is no necessary criterion of truth.

Regarding parsimony, Morgan (1890, p. 174) had previously written, "We do not know enough about the causes of variation to be rigidly bound by the law of parcimony." "Parcimony" is how Morgan and Hamilton spelled it.

### Was Morgan's Canon Anti-anthropomorphic?

Anthropomorphism as applied to animal cognition and behavior means attributing purportedly uniquely human abilities to nonhuman animals. Early on, as will be shown below, many authors wrote that Morgan's canon was anti-anthropomorphic. Such assertions prompted Wozniak (1993, p. x) to write:

Even worse [than equating Morgan's canon with the law of parsimony, Morgan's canon] is consciously anthropomorphic and based squarely on the adequacy of the psychologist's personal introspection.

*What was Morgan's view?* Two pages after stating his principle, Morgan (1894, p. 55) wrote.

As we have already seen, we are forced as men to gauge the psychical level of the animal in terms of the only mind of which we have first hand knowledge, namely the human mind. But how are we to apply the gauge?

Morgan continued on pages 56–59 to consider how to apply the gauge, and it clearly involved anthropomorphic reasoning by introspection and analogy.

### Was Morgan's Canon Anti-anecdotal and Anti-Romanes?

As will be shown below, many authors erroneously believed that at least part of Morgan's motive for the canon was to oppose Romanes' use of anecdotes as evidence for animal intelligence.

*Who was Romanes?* He was, perhaps, the first to consider animal intelligence in the context of Charles Darwin's theory of evolution. They were

friends, and when Darwin's editor for *On the Origin of Species* (1859) insisted that he reduce the manuscript's length, Darwin gave Romanes his chapter on "Instinct" intended for *On the Origin of Species* to use as he wished. Romanes included it as an Appendix to his book, *Mental Evolution in Animals* (1883).

*Mental Evolution in Animals* was Romanes' major theoretical work, and he based it primarily on data from *Animal Intelligence* (Romanes 1882). As few experimental data were available, Romanes had to rely mostly on published anecdotes. Romanes was aware of the pitfalls of anecdotes, and in the Preface to *Animal Intelligence* (p. vii), he wrote:

If the present work is read without reference to its ultimate object of supplying the facts for the subsequent deduction of principles, it may well seem but a small improvement upon the works of anecdote-mongers. But if it is remembered that my object in these pages is the mapping out of animal psychology for the purposes of a subsequent synthesis [viz., *Mental Evolution in Animals*], I may fairly lay claim to receive credit for a sound scientific intention, even if the only methods at my disposal may incidentally seem to a minister to a mere love of anecdote.

Also, in the Preface to *Animal Intelligence*, Romanes included a rigorous set of guidelines to be followed in selecting anecdotes. His main misstep was that he felt an obligation to quote observers' anecdotes as fully as possible, which usually included the observers' interpretations of the observed behavior. Such interpretations were rarely ones that Romanes accepted. Most of the observers were amateurs devoid of formal education in scientific methods.

For example, Romanes wanted to establish the fact that some ant colonies bury their dead. Romanes quoted several observers (including Sir John Lubbock, the eminent author of *Ants, Bees, and Wasps*, 1882) who reported seeing ants bury dead ants, which was all that Romanes wanted from the observations. However, in his perceived duty to quote observers' accounts fully, when feasible, he often also quoted their interpretations. One observer suggested that ants burying ants was a form of a funeral including a funeral procession; another observer's interpretation was that some

ants killed ants that shirked their duties and then buried them. Romanes' interpretation (*Animal Intelligence*, 1882) was, "This habit [ants burying ants]. . . is no doubt due to sanitary requirements, thus becoming developed as a beneficial instinct by natural selection" (p. 89). This is a reasonable interpretation, as sanitary colonies likely had better survival and reproductive rates than unsanitary ones.

Nevertheless, prominent early psychologists such as Margaret Washburn in her book, *The Animal Mind* (1908), cited and ridiculed the interpretation that ants hold funeral processions to bury their dead. Similarly, Wilhelm Wundt, the acknowledged founder of experimental psychology, in his book *Human and Animal Psychology* (translated from German to English in 1894) criticized Romanes' as follows:

While we admire the diligence with which the author [Romanes] has observed and collected the observations of others, we cannot but notice the unfortunate absence of the critical attitude in a field where it is especially desirable. Turn to the chapter on ants. . . (p. 343)

It seems clear that neither Wundt nor Washburn read Romanes' Preface to *Animal Intelligence* or his explanation of ants burying ants on page 89.

Regarding Morgan's opinion of using anecdotes, in his book, *Animal Life and Intelligence* (1891, p. 362), he wrote:

I do not propose to bring forward a number of new observations on the highly intelligent actions which animals are capable of performing. . . Mr. Romanes has given us a most valuable collection of anecdotes on the subject in his volume on *Animal Intelligence*.

Following Romanes' death in 1894, Morgan gave a eulogy for Romanes before the Royal Society of London in 1895 that included the following:

. . . by his patient collection of data, by his careful discussion of these data in the light of principles clearly formulated. . . Mr. Romanes left a mark in this field of investigation and interpretation which is not likely to be effaced.

His choice of words showed clearly that Morgan had read and respected Romanes' Preface to *Animal Intelligence*. It is ironic that Romanes'

name would be effaced as a result of the misuse of Morgan's canon.

## How Morgan's Canon Has Been Perceived by Historians of Psychology

Leading the pack, the most eminent twentieth-century historian of psychology, E. G. Boring, best known for his *A History of Experimental Psychology* and using the same words in both editions (1929, p. 464; 1950, p. 473), wrote: "For this reason [Romanes' alleged tendency to anthropomorphize]. . . the anecdotal method of Romanes has not only been discarded, but has become a term of opprobrium in animal psychology."

Thomas (2007) reviewed 32 history of psychology textbooks published from 1991 to 2005 (including multiple editions of a few of them), and he found that 18 misrepresented Morgan's canon as a canon of parsimony. Some of these and others misrepresented Morgan's canon as being anti-anthropomorphic and/or anti-anecdotal always referring to Romanes' use of anecdotes. Combining all three types of misrepresentation (or four if one counts being anti-Romanes separately), Thomas found only three textbooks (including two editions of one of them) among the 32 examined that provided generally accurate coverage of Morgan's canon. Additionally, Costall (1998, p. 18) wrote, "*The extent to which the intentions of Morgan's canon have been misinterpreted is astonishing.*" Wozniak (1993, pp. ix) wrote, "*It would be an interesting study in itself to trace the distortion of Morgan's views, in particular the attribution to Morgan of the principle of parsimony.*"

## A History of Misrepresentation of Morgan's Canon

Thomas (2001) conducted a study such as Wozniak suggested, and the main results are shown below. Intended to be representative and not exhaustive, this section includes quotations from researchers spanning at least 12 decades

who misrepresented Morgan's canon (full references for these quotations may be found in Thomas (1998, 2001, 2007). Section "[A History of Efforts to Correct the Misrepresentation of Morgan's Canon](#)" which follows has quotations from researchers spanning nine decades who tried to correct the misrepresentation of Morgan's canon. These sections may seem unduly tedious, but it is important to emphasize by examples the persistence and variety of misrepresentations of Morgan's canon as well as the largely disregarded efforts of scholars to correct the misrepresentation of Morgan's canon.

**Stanley (1896, p. 541)**

"His [Morgan's] caution is also admirable, but we do not think the law of parsimony is positive proof as he seems to urge."

**Mills (1899, p. 271)**

[In the context of Morgan's canon Mills wrote:] "Nor can I agree with those who maintain that we must always adopt the simplest explanation of an animal's action."

**Washburn (1908, p. 25)**

[After quoting Morgan's canon...] "In other words, when in doubt take the simpler interpretation."

**Holmes (1911, p. 159)**

"...it is well in general to be guided by the principle enunciated by Lloyd Morgan, which is a sort of special case of the law of parsimony."

**Warden (1927, p. 155)**

"The canon of Morgan... was an attack against the prevailing anthropomorphism... The canon is merely the law of parsimony applied to animal psychology."

**Adams (1928, p. 241)**

[After quoting Morgan's canon...] "This is plainly intended as an adaptation to the problems of animal psychology of the general Law of Parsimony..."

**Boring (1929, pp. 464–465)**

[Morgan] "...who undertook to offset the anthropomorphic tendency in the interpretation of the animal mind by an appeal to the 'law of parsimony.' This law applied to animal psychology is often known as 'Lloyd Morgan's canon.'"

**Pillsbury (1929, p. 283)**

"He [Morgan] is deserving of credit for urging what he calls the law of parsimony in the interpretation of mental phenomena in animals. . ."

**Flugel (1933, pp. 123–124)**

The reaction started with Lloyd Morgan, who, in the [eighteen] nineties, endeavored to combat the dangers of the anecdotal method by the "law of parsimony," according to which we must always explain animal behavior in terms of the simplest mental processes that will account for the facts.

**Waters (1939, p. 534)**

Morgan's canon was offered as just such a check [against the use of anecdotes and anthropomorphism]. Its immediate effect was to outlaw at once any description of animal behavior as due to mental processes.

**Harriman (1947, pp. 225–226, 255)**

[These definitions appeared in Harriman's *The New Dictionary of Psychology*.]

Morgan's canon: C. Lloyd Morgan's axiom to the effect that the simplest explanation of all known facts is the best hypothesis or theory. It is a restatement of the principle expounded by William of Occam (c. 1325) and known as Occam's razor. Parsimony, law of: Lloyd Morgan's statement (1900) that animal behavior should be described in the simplest possible terms. It is an application of Occam's razor to animal psychology. Occam (1280–1349) had said that entities should not be multiplied beyond necessity [sic]; and Morgan accepted this view, indicating that anecdotes, attribution of human mental activities to animals, and projection of introspections have no place in animal psychology.

**Munn (1950, pp. 1–2)**

"Lloyd Morgan... advocated a curb on anthropomorphic speculation... His well known principle of parsimony for students of animal behavior read as follows:..."

**Caldwell (1960, p. 401)**

Morgan gave comparative psychology his interpretation of the law of parsimony, which curbed the tendency of observers of animals to anthropomorphize.

**Dewsbury (1973, p. 9)**

He proposed a law which has been variously termed Occam's razor, the law of parsimony, and Lloyd Morgan's canon. . .Lloyd Morgan's canon seems applicable today. If alternative explanations appear truly equal, the simpler is to be preferred until data require postulation of more complex processes.

**Dewsbury (1978, p. 10)**

Morgan is best known for opposing unbridled anthropomorphism. According to the often-cited "law of parsimony" or "Lloyd Morgan's canon. . ." The admonition that we should strive to accept the simpler of two equal alternative explanations is certainly good advice for many situations.

**Denny (1980, p. 4)**

"C. Lloyd Morgan, author of the famous Canon of Parsimony, dealt explicitly with animal behavior."

**Griffin (1981, p. 118)**

[Below and elsewhere (p. 99), Griffin accepted the interpretation that Morgan's canon is a canon of parsimony. However, Griffin (p. 131) also accepted Miller's view (1962) that the canon was not anti-anthropomorphic.]

This [Morgan's canon] has been widely interpreted as requiring that complex functions should not be postulated if a simpler explanation will suffice. That is the widely accepted principle of parsimony. . .

**Boakes (1984, p. 40)**

The canon can be seen as simply the application of the general law of parsimony to explanation of behavior. Nevertheless, Morgan did not justify it on these terms but on the grounds of evolutionary theory.

**Dewsbury (1984, p. 188)**

"The law of parsimony and Morgan's canon are two closely related principles."

**Epstein (1984, pp. 122–123)**

Morgan was a British psychologist and biologist who, in *An Introduction to Comparative Psychology*, published in 1894, challenged the tendency of some naturalists of his day to attribute human characteristics to animals. . .Morgan was no less a mentalist than Romanes, but he took a more conservative stand. Just as evolution had produced organisms that varied from the simple, to the complex, he argued, so must it have produced minds that varied from the simple to the complex. It would therefore be presumptuous of us to infer higher mental activities in animals where simpler ones would do. He expressed this in his famous Canon, sometimes called the Canon of Parsimony.

**Grier and Burk (1990, p. 52)**

Among his other contributions, he rejected anecdotalism and undisciplined anthropomorphism in the interpretation of behavior in other animals. He called for a principle of theoretical parsimony (i.e., the simplest explanation) which became known as Morgan's canon. . .

**Baenninger (1994, p. 805)**

[Baenninger's was a book review titled "A Retreat before the Canon of Parsimony." The book being reviewed was Donald R. Griffin's book, *Animal Minds*.]

"C. Lloyd Morgan's Canon of Parsimony is not mentioned in the index but it casts a long shadow over this important book."

**Barrows (1995)**

[Barrows' quotations appear in his book, *Animal Behavior Desk Reference*, which may be compared to a dictionary or an abbreviated encyclopedia. Relevant to the present work were the entries for "Morgan's canon," "Ockham's razor," and "law of parsimony." The citations of Dewsbury were Barrow's.]

[p. 308] Morgan's canon. [after quoting the canon, the entry continued]. . .that is, one should interpret data using the most parsimonious explanation (Dewsbury, 1978, 10). . .Syn. Law of parsimony, (Lloyd) Morgan's canon (Dewsbury 1978, p. 10). See law: law of parsimony. Cf. Ockham's razor. [p. 358] Ockham's razor. [included] Cf. Law: Law of parsimony; Morgan's canon; simplicity. [p. 385] law of parsimony. [included] Cf. Morgan's canon, Ockham's razor.

**Bekoff and Allen (1997, p. 326)**

[After quoting Zabel et al. who wrote, "One must be cautious about inferring complex cognitive processes when simpler explanations will suffice," Bekoff and Allen considered Zabel et al.'s statement to be equivalent to Morgan's canon. With the aid of an anonymous reviewer, Bekoff and Allen tried to distinguish Morgan's canon from parsimony, but they did not acknowledge that the anonymous reviewer was wrong.]

The statement by Zabel et al. is a paraphrase of Morgan's (1894)

Canon. . . It is possible that Morgan's Canon which is concerned with the complexity of processes should be distinguished from parsimony which is concerned with the number of processes needed to explain a given behavior (as an anonymous reviewer noted).

**Knoll (1997, p. 20)**

Those with a fondness for neatly organized historical eras might say that Morgan's Canon, as it is called, marks the end of the anthropomorphic strategy in psychology and the beginning of twentieth century behaviorism. [Paragraph break] However, Morgan's Canon is a double-edged sword. . . It can cut up as well as down. . . if we cannot anthropomorphize the animals, we cannot anthropomorphize ourselves either.

**Macphail (1998, p. 80)**

What animal psychology needed, then, was. . . the theoretical discipline to interpret the results in as parsimonious a way as possible – a discipline crystallized by the British psychologist Conwy Lloyd Morgan (1852–1896) in his well known canon. . .

**Dewsbury (2000, p. 751)**

In his classic textbook, Morgan (1894) outlined his famous canon that an animal's behavior should be interpreted in terms of the psychologically simplest processes consistent with the data. Morgan's canon, and its related concept, parsimony, spread widely during this period.

## **A History of Efforts to Correct the Misrepresentation of Morgan's Canon**

Again, intended to be representative and not exhaustive, Thomas (2001) presented quotations

across nine decades by those who tried to correct the misrepresentations of Morgan's canon (quoted here from Thomas 2001, where, again, references for the quotations may be found). In a few instances, the following were modified slightly when appropriate to fit the present context.

**Adams (1928, pp. 241–242)**

[Given the Adams' (1928) quotation in the previous section, this may be a dubious example of an effort to correct the misrepresentation of Morgan's canon.]

Morgan's canon, however, instead of being as commonly considered, a special case of the law of parsimony, is not related. . . and may on occasion work to exactly opposite effect. . . Here is Morgan trying to adapt the law of parsimony to psychology and violating it in the same breath by "multiplying entities" making quantities of unnecessary assumptions.

**Nagge (1932, pp. 492–493)**

[Nagge appropriately explained the canon and also addressed issues related to the law of parsimony. The phrases "undergone a transformation" and "come to be known. . . as the law of parsimony" was seen by Nagge as misrepresenting Morgan's canon.]

Lloyd Morgan. . . has laid down a canon of interpretation which has come to be known to psychologists as the law of parsimony. . . This canon seems to have undergone a transformation in general psychological usage until it might now be tentatively expressed thus: of any possible number of explanations of an animal act the simplest possible explanation should be employed. . .

**Newbury (1954, p. 73)**

[Before concluding as quoted below, Newbury cited ten references where the canon had been misinterpreted as a version of the law of parsimony, seven references (including five of the parsimony-10) interpreted the canon as a doctrine of simplicity, and four (all in the parsimony-10) related Morgan's canon to Occam's razor. Newbury also cited other forms of misinterpretation, and he provided a detailed analysis of how Morgan's canon should be interpreted.]

Aside from their historical inaccuracies, many current misinterpretations of Morgan's Canon have *sui generis* failed to take advantage of possible logical developments. Without contending that Morgan's methodology represents the last word, one can recognize in it some of the essentials for integrating modern introspective and comparative psychology. Whether this gain through historical continuity can be realized depends upon an accurate and significant interpretation of that methodology, including the Canon.

### Miller (1962, pp. 214–215)

Subsequent generations of psychologists have called this Lloyd Morgan's canon and have assumed that what he must have meant was that anthropomorphism – attribution of human characteristics to gods or, as in this case animals – is unscientific. A glance into Morgan's books, however, is enough to refute this assumption. Like all of his contemporaries, Morgan took it for granted that since the only psychical faculties we can know anything about directly are our own, "introspection must inevitably be the basis and foundation of all comparative psychology."<sup>3</sup> [Footnote 3 is Miller's, and it referred to "Morgan (1894, p. 37)."] Any human introspection would necessarily be anthropomorphic; all that Morgan hoped for were a few reasonable rules for playing the game.

### Gray (1963, pp. 221–222)

[Gray provided a reasonable analysis of what Morgan intended, identified some of the misinterpretations of Morgan's canon, and ridiculed them as follows.]

Boring, Flugel, and Skinner have referred to the Canon as a law of parsimony. Had it been such a law, surely it would have reduced Morgan's entities; instead, it was compatible with their multiplication. [Paragraph break] Likewise, Thorpe's assumption that the Canon is related to Occam's razor is merely gratuitous. [Paragraph break] Waters' statements [e.g., Waters 1939, in previous section] are not only contrary to historical fact, but are also incorrect.

### Singer (1981, p. 268)

[Singer's parenthetical "*Animal Behavior*" below referred to Morgan's book with that title published in 1900. Unfortunately, Morgan's emendation of Morgan's canon in *Animal Behavior* has been almost totally ignored, and errors of one kind have been replaced by errors of the other.]

Some workers took this principle too seriously and would not allow any interpretation of an advanced process, even if suggested by the evidence, and in 1900 Lloyd Morgan was obliged to add the following rider to his canon: 'To this it may be added – lest the range of the principle be misunderstood – that the canon by no means excludes the interpretation of a particular act as the outcome of higher mental processes if we already have independent evidence of their occurrence in the agent (*Animal Behavior*)'.

### Costall (1993, pp. 116–117)

[Costall's entire paper, listed among the references here, is a discussion of the misrepresentation of Morgan's canon. Hence, selecting excerpts to quote is difficult. Please consult Costall for footnotes omitted from the following quotations.]

Later commentators have consistently represented this [Morgan's canon] as an appeal to Occam's razor, a principle of parsimony; they have taken it as an outright prohibition against treating animals as anything other than mechanical automata; and they have characterized it as a rejection of anthropomorphism. [Six paragraphs later.] Morgan's canon as currently misconstrued has very much the character of a myth. Indeed, many of those wishing to counter the implications of this myth have themselves managed to perpetuate the myth itself. It has evidently been highly resistant to several attempts at correction. Indeed the two most informative recent accounts of Morgan's work make no attempt to question the accepted view of the canon.

### Wozniak (1993, pp. ix–x)

[After quoting examples where Skinner (1938), Griffith (1943), and Harriman (1947); see previous section) associated Morgan's canon closely with the law of parsimony, Wozniak wrote:]

One thing is virtually certain – neither Skinner, nor Griffith, nor Harriman could ever have read Lloyd Morgan. Even if one set out deliberately to distort the meaning of Morgan's canon, it would be virtually impossible to do so with greater success. Morgan's canon is not a principle of parsimony, it was not formulated as a guide to the description of behavior, it does not dispense with mental faculties, it is not an appeal to the observable, and it is not meant to be specific to animal psychology. Although earlier writings may also have misinterpreted Morgan in this fashion, it seems likely that Boring [Boring, E. G. (1929). *A history of experimental psychology*. New York: Century] was one of the more influential culprits. See especially pp. 464–465.

### Costall, Clark, and Wozniak (1997, p. 66)

Morgan's canon has been consistently overinterpreted. It was not a prohibition against the application of intentionalistic descriptions to animals, but rather an attempt by Morgan to put 'anthropomorphism' on a more secure scientific footing. (Costall 1993)

### Costall (1998, p. 18)

When Morgan realized his intentions were being misinterpreted, he added the clarification that "the Canon by no means excludes the interpretation of a particular activity in terms of the higher mental processes, if we already have independent evidence of the occurrence of these higher processes in the animal under observation" (Morgan 1903, p. 59). Nor, contrary to most accounts, was the canon, in any simple sense, an appeal to the principle of parsimony – an invitation to be economical with the truth... His serious point was that there were very good Darwinian reasons for supposing that animals should vary in the nature of their mentality. The canon was, therefore, Morgan's attempt to put "anthropomorphism," the psychological approach to animals, on a secure scientific footing (Costall 1993). [Paragraph break.] The extent to which the intentions of Morgan's canon have been misinterpreted is astonishing.

### Thomas (1998, p. 156)

Clearly Morgan's canon was intended to be a stricture to guide the interpretation of evidence pertaining to psychological processes in animals, but the misrepresentation of that canon that occurred early...and that continues in the present...is that it was a canon of parsimony or simplicity.

## A Proper Approach to Use Morgan's Canon

As noted earlier, Morgan realized early that his intended use of the canon was being misunderstood, so in 1903 he revised it for clarification. It is useful to repeat it here.

In no case is an animal activity to be interpreted in terms of higher psychological processes, if it can be fairly interpreted in terms of processes which stand lower in the scale of psychological evolution and development.

"Higher" and "lower" meant "newer" and "older," respectively, in terms of the evolutionary development of psychological processes. Unfortunately, Morgan was not clear about what the components of scale of psychological processes were. One may get weak hints from some of his chapter titles (identical in the 1894 and 1903 editions) and the order in which they appear. However, other chapter titles [e.g., "Memory" and "The Sense-Experience on Animals"] are mixed among the ones that give the best hints of a scale of processes, namely, Chapters IV "Suggestion and Association," XII "Instinct and Intelligence," XIII "The Perception of Relations," XIV "Do Animals Perceive Relations," XV "Conceptual Thought," and XVI "Do Animals Reason?." In 1894 and 1903, Morgan appeared to have concluded that the evidence then did not show that animals perceived relations, had conceptual thought, or were capable of reason. However, he acknowledged that future research may provide confirming evidence for one or more of these, as is the case (e.g., Thomas 1996).

Meanwhile, Romanes' *Mental Evolution in Animals* (1883) included a foldout chart that shows his self-admitted, tentative construction of "The Psychological Scale" as well as "Products of Emotional Development" and "Products of Intellectual Development." Each of these headed a column with many rows with content entries (more below). The chart also includes an illustrative "tree" that is too complex to summarize here. The column headed "Products of Intellectual Development" has 17 numbered categories where 1 was intended to be the earliest and 17 was intended to be the most recent in evolutionary development. A few examples will be listed below in order of their numbers in the chart from the column headed "Products of Intellectual Development" together with examples from the adjacent row in column headed "The Psychological Scale." The latter consisted of Romanes' identification of representative animal classes, orders or, in some cases, examples of animals that he believed to have achieved a particular level in the scale of "Products of Intellectual Development." Following are a few examples:

- 08. Association by contiguity – Mollusca
- 10. Association by similarity – Fish and Batrachia [Amphibia]
- 13. Communication of ideas – Hymenoptera
- 16. Use of tools – Monkeys and Elephant

If 13 seems generous, recall that later research showed that bees use the “waggle dance” to communicate distance and location of sources of nectar.

Romanes' foldout chart follows the Table of Contents, and one must read the book to better understand his reasons for the entries he made in the chart. Boakes reproduced Romanes' chart in his book, *From Darwin to Behaviorism: Psychology and the Minds of Other Animals* (1984), as did Murray (1989) in his *A History of Western Psychology*. Murray wrote:

Romanes. . .book, *Mental Evolution in Animals*, is now being recognized as one of the most important books in the history of psychology because it attempted to unify all the research on animal instincts and animal intelligence into a single evolutionary scheme. (p. 263)

Morgan (1891) commented on Romanes' chart in a footnote on page 478 as follows:

I ought not pass over without notice the ‘psychological scale’ which Mr. Romanes introduces to a table prefixed to ‘Mental Evolution in Animals.’ It would be unjust to criticize this too closely, for it is admittedly provisional and tentative. If such a scheme is to be framed, I would suggest that the various phyla of the animal kingdom be kept distinct. I question, however, whether anyone can produce a scheme which any other independent observer will thoroughly endorse.

## A Modern Role for Morgan's Canon?

Karin-D'Arcy (2005) provided critical discussion of modern roles for Morgan's canon as seen by numerous well-known contemporary researchers, and she provided commendable recognition of the history of the misrepresentation of Morgan's canon. Risking overgeneralization here, most modern roles for Morgan's canon as reported by Karin-D'Arcy are reasonably consistent with Morgan's and Romanes' views in section

“A Proper Approach to Use Morgan's Canon” here pertaining to the evolutionary development of a psychological scale of intellectual processes. However, some modern investigators insist on a role for simplicity even when they acknowledge that was not what Morgan meant by the canon. The view here, to be documented in the next section, is that *determining simplicity* is so fraught with pitfalls and limitations that it is useless in psychological science.

## Simplicity in Philosophy

Emblematic and representative of articles and books by philosophers of science on the subject of simplicity as a basis for choosing between or among alternative explanations, theories, etc., 50+ years ago was Bunge's (1963) *The Myth of Simplicity: Problems of Scientific Philosophy*. For psychological science, perhaps, the most recurring problem with simplicity as a criterion for choosing among alternative explanations is that most explanations involve unrecognized or hidden assumptions that confound being able to determine which is the simplest explanation. Bunge's view that simplicity was a myth or, at least, that simplicity is almost forbiddingly capable of being defined or applied continues 50+ years later. For a recent example, Fitzpatrick (2015, pp. 39–40) wrote:

The putative role of considerations of simplicity in the current practice of science gives rise to a number of philosophical problems, including the problem of precisely defining and measuring theoretical simplicity, and the problem of justifying preferences for simpler theories. As this survey of the literature on simplicity in the philosophy of science demonstrates, these problems have turned out to be surprisingly resistant to resolution, and there remains a live debate amongst philosophers of science about how to deal with them.

Scorzato (2013, p. 2867) addressed some problems associated with assumptions and language that prohibit the ability to decide which explanation is simplest.

Simple assumptions represent a decisive reason to prefer one theory to another in everyday scientific praxis. But this praxis has little philosophical

justification, since there exist many notions of simplicity, and those that can be defined precisely strongly depend on the language in which the theory is formulated. The language dependence is a natural feature – to some extent – but it is also believed to be a fatal problem. . . in fact, the concepts that enable a very simple formulation, are not necessarily measurable. . . precisely those concepts that make the theory extremely simple are provably not measurable.

If Fitzpatrick's and Scorzato's observations and conclusions are not enough to make a working behavioral scientist dizzy with uncertainty about using parsimony or simplicity as a criterion to choose among alternative explanations of behavior, Sober's (2015) *Ockham's Razors: A User's Manual* should persuade behavioral scientists to surrender completely any attempt to use simplicity to choose among alternative explanations.

### **Simplicity Aside: How to Approach Explanation in Animal Cognition Research**

As mentioned above, mere perusal of a few issues in 2018 of the journal, *Animal Cognition*, revealed that researchers are studying animals ranging from insects to apes, and I am confident that further perusal will reveal research on animals taxonomically lower than insects. In that quick perusal, topics being investigated included "vigilance decrement" (spiders), "boldness" (fish), "jealous behaviors" (dogs), "causal reasoning" (crows), "facial recognition" (monkeys), and "intuitive optics" (chimpanzees) to mention only a few.

Sir Francis Bacon's (*Novum Organum*, 1620) consideration of "idols of the market place" showed the hazards for science that are inherent in the fallibilities of language, and Gregory Bateson (*Steps to An Ecology of Mind*) wrote critically about "linguistic muddling." If they were alive, they would be overwhelmed by the linguistic morass that psychological science has created. It may be hopeless, but to begin to hope to reduce this morass, the following are recommended.

### **Understanding Intervening Variables (IVs) and Hypothetical Constructs (HCs)**

An important article that all psychological scientists should read and incorporate into their understanding regarding concepts and explanations is McCorquodale and Meehl (1948). Seventy years later it seems apparent that most psychological scientists do not understand their distinction between IVs and HCs. Here is a fundamental quotation.

At present the phrases 'intervening variable' and 'hypothetical construct' are often used interchangeably, and theoretical discourse often fails to distinguish what we believe are two rather different notions. (p. 106) [Later]. . . the only rule for intervening variable is that of convenience, since they have no factual content surplus to the empirical functions they summarize. . . In the case of the hypothetical constructs, they have a cognitive, factual reference in addition to the empirical data, which constitute their support. (p. 107)

Elsewhere in the article, it is clear that the meaning of an IV is limited to observables, and as concepts or explanations, an IV's meaning is no more or less than the observations that support an IV's existence as a concept. At most, IVs are shortcut terms invented or adopted from common language whose meanings are defined by a multiplicity of observables. On the other hand, a HC as an explanatory concept implies something beyond the observables, something that is presumed to exist. Atomic and subatomic particles in physics are HCs, and a good example in biology was the "gene." The HC "gene" came into use in 1909, long before its physical makeup as DNA had been determined.

One is challenged to identify any concept in animal cognition research that is not an IV. As such and despite common practice, IVs cannot be reified. For example, they cannot be causes or effects, because their existence is limited to the observables that define them. Examples used here for illustrative purposes of IVs in animal cognition research, "boldness," "causal reasoning," and "facial recognition" (chosen among several others listed in first paragraph of section "[A Modern Role for Morgan's Canon?](#)"), were gathered via a quick survey of a couple of 2018 issues in the electronic journal *Animal Cognition*. Other IVs ad

nauseam may be seen in *Animal Cognition* and other contemporary journals that publish research in animal cognition.

### The Brain and Intervening Variables (IVs)

Close study of functional neuroanatomy textbooks (e.g., the several editions of Alf Brodal's *Neurological Anatomy* or Malcolm B. Carpenter's *Human Neuroanatomy*; over the years Brodal had a successor, and Carpenter had coauthors and a successor), other textbooks in functional neuroanatomy, and articles such as Diamond (1979) should result in the conclusion that all brain functioning reduces to three fundamental types of processing: sensory, memory, and effector. *All other processes reduce to one or combinations of these three.* These three processes interact continuously in the brain and effect physicochemical changes in the brain. The brain is never exactly the same physicochemically from moment to moment, nor are the associated IVs exactly the same from moment to moment.

Figure 1 shows how IVs exist only as shorthand terms to summarize each IV's associated antecedent and consequent observables.

Figure 2 emphasizes that the brain and the IVs used in this example (and all other IVs) are never exactly the same from moment to moment.

Strictly speaking, a radical behaviorist might insist correctly that the precise meaning of each IV is limited to the antecedents and consequents associated with a specific experiment or controlled observation. However, to cite but one example, we know that many IVs (e.g., "fear") may be used more generally based on many different experiments or controlled observations involving different observables. Such different uses of "fear" have in common antecedents and consequents associated with potential bodily harm or death. Of course, one does not have to be bitten by a poisonous snake to fear being bitten by a poisonous snake, because memories associated with learning about the experiences of others provide us with sufficient information to be fearful of being bitten by a poisonous snake. It cannot be iterated enough that an IV's meaning is limited to the observable antecedents and consequents that define it and that IVs can never be reified as causes and effects or have any other characteristics of entities that have material existence.

### Hazards of Emergentism in Psychological Science

In her aptly titled critique, "Clever Animals and killjoy explanations in comparative psychology," Shettleworth (2010, p. 477) quoted Holldobler and Wilson as follows:

**Morgan's Canon, Fig. 1** The brain at a moment in time when physico-chemical events associated with sensory, memory and effector processing are constantly interacting and effecting new physico-chemical changes. To an extent, these internal observable antecedents, IOAs, or consequents,

IOCs, may be observed via chemical sampling, electrical recordings or brain imaging, or manipulated via chemical or electrical stimulation or targeted ablations. "Tagging along" with the brain's activity are the Linking IV Concepts

**Morgan's Canon, Fig. 2** A dynamic representation of the brain and its associated External Observable Antecedents (EOAs) and Internal Observable Antecedents (IOAs) symbolized as open arrows and External Observable Consequents (EOCs) and Internal Observable Consequents (IOCs)

symbolized as solid arrows. As indicated, the EOCs at one moment in time become part of the EOAs at the next moment in time. The brain, physically, is never exactly the same from moment to moment, thus the meaning of linking concepts are not exactly the same from moment to moment

The extremes of higher-level traits may at first appear to have a life of their own, one too complex or fragile to be reduced to their basic elements and processes by deductive reasoning and experiment. But such separatist holism is in our opinion a delusion, the result of insufficient knowledge about the working parts and processes.

This raises nicely the issue of the hazards of emergentism.

Emergentism, although not by that name, developed most strongly with the nineteenth-century British associationist philosopher, John Stuart Mill. John Stuart Mill argued against his father's, John Mill's, "mental mechanics" using a paradigm the younger Mill named "mental chemistry." This was illustrated by John Stuart Mill's example of water. He argued that water has emergent properties, namely, that water has properties that cannot be reduced to its constituent elements, hydrogen and oxygen. As opposed to John Mill's "the whole is equal to the sum of its parts," John Stuart Mill asserted that "the whole is greater than the sum of its parts." If water seems to have emergent properties, it is likely because we do not yet understand the complete physical and chemical properties of oxygen and hydrogen.

That "the whole is greater than the sum of its parts" was perpetuated by the Gestaltists Max Wertheimer, Wolfgang Kohler, and Kurt Koffka beginning early in the twentieth century and has been advocated for animal cognition research in recent years by Duane Rumbaugh and colleagues among others. Thomas (1999) presented a rebuttal

of Rumbaugh and colleagues in 1999 in a symposium in which Rumbaugh and two colleagues participated at the Southern Society for Philosophy and Psychology.

A quotation from Guyer (1931) used by Thomas (1999) is also useful here. It is slightly modified here as explained below to show that "emergentism" in animal cognition is deemed parallel to the role that "vitalism" once had in biological science. Before significant progress could be made in biology, biology had to rid itself of vitalism. In the portions quoted here from Guyer (1931), "emergentism" or related terms have been added in brackets to make explicit the parallels between the hazards of "vitalism" for biological science and the hazards of "emergentism" for psychological science.

Are the characteristics which mark off living from nonliving matter explainable by physics and chemistry and the known laws of matter or is there something else?... Two opposing interpretations have been suggested; one known as vitalism [emergentism], the other as mechanism. By vitalism [emergentism] is meant a directive tendency beyond the inherent properties of mere molecules or chemical elements which manifests itself in and is peculiar to the living organism. . . They [vitalists and emergentists] believe they find evidence of purpose in life-activities and that such activities are inexplicable on the basis of mere physics or chemistry. . . admitting that many of the phenomena seen in living things are yet unexplained or are even inexplicable in terms of our present knowledge of chemistry and physics, the mechanist points out that with our advancing knowledge in these fields many

of the processes originally claimed by vitalists [emergentists] to be distinctively vital [emergent] have been shown to be physical or chemical and that continual progress is being made by mechanistic methods. . . . Mechanists believe it is simpler and more accurate to regard life as process or function rather than as a separate essence, and to consider living matter as ordinary matter so arranged as to become a metabolic mechanism. . . .

The controversy, though changing its form from time to time, has been carried on ever since the days of Aristotle and there seems no prospect of agreement in the near future. The problem may be insoluble. As our knowledge of fundamental life processes has advanced, the vitalist [emergentist] has been forced to abandon one position after another, but there is still such a great unexplained residue of facts relating to the constructive and coordinating processes of living matter that he still has abundant material for argument. As a practical working program, however, it is well to note that the science of biology has advanced mainly as it has been able to explain its phenomena in mechanistic terms, and that there is undoubtedly much yet that can be so explained. To rest content with merely attributing vital [emergent] phenomena to some sort of "vital principle" [emergent] is in effect to give up the problem, and such an attitude of mind can lead only to scientific stagnation. (Guyer 1931, pp. 22–23)

## Concluding Remarks

It is hoped that all misrepresentations of Morgan's canon (equivalency with Ockham's razor, parsimony, and simplicity; being anti-anthropomorphic, anti-anecdote, and anti-Romanes) can now cease and rest in peace. Greater consideration of Morgan's canon's association with a study of the evolutionary development of cognitive abilities, together with Romanes *Mental Evolution of Animals*, might lead to a useful way to assess and rank cognitive abilities in animal cognition research.

Finally, it is hoped that researchers in animal cognition will pay greater heed (a) to the futility of using simplicity as a criterion to choose among alternative explanations; (b) to the importance of McCorquodale's and Meehl's distinction between intervening variables, IVs, and hypothetical constructs, HCs; and (c) to the limitations of what we can and cannot know about the brain and IV concepts in animal cognition research.

Animal structure; Body type; Difference of form; Shape; Zootomy

## Introduction

The word morphology derives from the Greek μορφή, morphé, meaning “form,” and λόγος, lógos, meaning “word, study, research.” In biological sciences, morphology is responsible for the study of form, shape, and structure of extinct and extant organisms. Even though studies on morphology have been conducted far before the eighteenth century, the term was first publicly employed by W. Goethe in a medical handbook in 1800, with the underlying meaning of study in organic design or form (Richards 2008; Kardong 2008). However, the term morphology (=morphologie) was already used by Goethe in 1796 in a correspondence with his personal friend, the poet Friedrich Schiller. In the first number of the first volume of Goethe's classic publications

named *Zur Morphologie* (1817), he meant especially by the term as the study of organic forms, both external and internal, and the development of such structures (Richards 2008).

Inspired mostly by Goethe's studies and definitions, several physicians and naturalists (e.g., K. Friedrich, L. Oken, C. Carus, R. Owen, E. Haeckel) have posteriorly complemented and advanced several concepts, terms, and theories that are currently used in morphological studies (Richards 2008). Morphological studies have been complemented by several fields in sciences, such as histology, anatomy, cytology, and embryology (Kardong 2008). Above all definitions given to the term since its proposition, morphology raises questions about structure and offers a method to address these questions, seeking to explain organisms design by elucidating the reasons and processes that produce their basic structural plan (Kardong 2008).

## Morphology Versus Anatomy

The concepts and utilizations of the terms “morphology” and “anatomy” have been used interchangeably in biological sciences. For some, internal morphology may represent a synonym of anatomy, contrasting with external morphology, which does not demand any invasive procedure for structure visualization. However, they represent distinct, yet similar areas of study considering an organismal structure and organization and should not be considered as synonyms. The term anatomy is composed of two Greek words that mean cutting up. In other words, the term anatomy should be used to refer to the organismal structure, based on observations of structures capable of demonstration (Snodgrass 1951). For instance, when analyzing the structure of an animal intestine, one should report the tissue components, cell organization, microstructures, etc. that demanded any kind of technique for its acquisition. On the other hand, morphology includes several hypotheses and background theories associated with the animal structure and shape, such as evolutionary assumptions that are highly multidisciplinary. Morphology, therefore, should be applied to studies that consider

the animal structure – derived from evidence based, for example, on anatomy and embryology – and might discuss the evolutionary means that lead to those structures. Such evolutionary means might include several concepts that associate the anatomy of individual to the means that lead to such body plans.

## Form and Function

Animal bodies and design must address physical and biological demands. For instance, gravity acts on all structures of terrestrial animals, as a consequence, heavy vertebrates must exert much effort in locomotion. Differences in size necessarily lead to differences in performance and design. As body size changes, the demands on various body parts change disproportionately.

Form is solely the appearance, configuration, or shape of a structure, while the function of this structure is its action or how it works (Bock and Wahler 1965). Size and shape are necessarily linked, and the consequences affect everything from metabolism to body design. Thus, change in size inevitably requires a change in form, known as scaling, a compensatory adjustment in proportion to maintain performance with changes in size. Furthermore, a surface area increases rapidly with increase in size, scaling in proportion to the square of the linear dimensions. Volume (mass) is even more affected, increasing by the cube of linear dimensions. Inevitably, larger organisms have relatively greater mass with which to contend and, consequently, the supportive and locomotor systems must be built differently and stronger to meet the accompanying physical demands (Kardong 2008).

Shape changes in proportion to size, termed allometry, are common during the growth of an organism. Shape is important, for example, in aquatic animals. Thin shapes help reduce drag in aquatic environment, while specific position like turning broadside allows a fin or flipper to use profile grad to generate forces. A streamline shape encourages smooth, non-separating flow.

The study of the function of structural features of organisms opens up a new realm in the analysis

of biodiversity. Much attention has been focused on the morphological parts of organisms and on the geographic distribution of species, but in comparison, relatively little is known about function diversity. Although the form-function relationship is one of the oldest areas in biology, relatively little attention has been paid to the function side of this dichotomy. Accordingly, disciplines analyzing organismal function are traditionally reductionist, mechanistic, and experimental. Such analyses have provided insights into many features of organismal design and have been instrumental in the spread of new ways of thinking about how organisms are built. For example, the use of dimensional analysis and scaling to evaluate mechanistic hypotheses about musculoskeletal function has contributed to a number of significant insights into how birds fly. Also, the now widespread awareness of the importance of fundamental physical relationships such as surface-area-to-volume ratios for understanding organismal design is in large measure due to the contributions of comparative physiologists.

## Basic Morphological Concepts

Several concepts have been developed in order to analyze design, as the concepts of form, function, and evolution. Even though terms associated with such concepts have just been proposed in the nineteenth century, their meanings as currently applied have only been defined after Darwin's theory on common ancestry (Kardong 2008). Some of the most useful of these terms address (1) similarity, (2) symmetry, and (3) segmentation (Kardong 2008).

Regarding similarity, the terms homology, analogy, and homoplasy have been proposed mostly based on three criteria: ancestry, function, or appearance. Homologous structures which similarity are due to common ancestry. Homoplastic structures look alike, but that is not due to common ancestry, while analogous structures do not feature a common ancestor, and may not be similar but exhibit similar functions. As an example, wings of butterflies are analogous to bat wings as they both perform the same function (=fly),

but do not have a common winged ancestral. Thus, parts may be similar in ancestry, function, and/or appearance; however evolutionary evidence might contribute on relevant data for their understanding.

With respect to symmetry, it refers to the plan of the organism in relation to the environment, as well as its distinct regions. The two main types of symmetries applied in zoology regard radial and bilateral symmetries, with the former representing a body laid out equally from a central axis (e.g., starfish) and the latter regards individual that only the midsagittal plane divides the body into two mirrored images (e.g., whale). Organismal regions are described in many ways, frontal planes divide bilateral organisms in dorsal and ventral sections, a sagittal plane splits into left and right, and a transverse plane (=coronal) divides into anterior and posterior portions. Finally, segmentation deals with a body plan that includes repeating or duplicated sections in the organism structure. Examples are the backbone composed of repeated vertebrae (vertebrates) and the body of several arthropods (Hannibal and Patel 2013).

## Assessing Morphological Data: Fields of Study, Methods, and Techniques

Several tools have been developed since the first studies conducted on organismal morphology, which can be conducted depending on the researcher goal (Kardong 2008). The earliest tool developed by morphologists was direct **dissection** (Kardong 2008). First dissections were conducted in humans and can be traced back thousands of years ago, at least to 1600 BC in two ancient Egyptian papyri that distinguishes organs such as the heart, liver, spleen, kidney, and others. Even though the dissection practices conducted by Egyptians did not directly aim to contribute on the knowledge on the human anatomy, the continuous practices of mummification contributed to it. It was only in 500 BC that Alcmaeon of Croton, an ancient Greek philosopher and medical theorist, dissected the first human body, providing the first insights on the origin of physiological processes of feelings, mostly associated with the

**Morphology, Fig. 1** Cleared and stained skull of a threadsnake (*Trilepida salgueiroi*) in dorsal (a) and ventral (b) view, lower jaw in medial view (c) and ventral view of the posterior trunk vertebrae, cloacal vertebrae and caudal vertebrae (J. J.)

brain (Singer 1957). The earliest animal dissections were performed by Galen, who dissected several mammals (e.g., monkeys, cows, and dogs) in 150 AC. Much has been improved regarding organismal dissection, and different methods/techniques have been developed for specific elements in the body. For example, techniques for bone examination involve soft tissue removal and bone cleaning, with a wide variety of methods or techniques for bone preparation (Dawson 1926; Onwuama et al. 2012). Bone preparation might be accomplished by maceration, by removal of soft tissues with the aid of water/reagents, or by the exposure to flesh-eating bugs – *Dermestes* spp. In maceration, specimens are left in sealed containers to the natural effect of putrefaction, with constant removal of putrefied tissue. In manual removal of soft tissues, specimens might be immersed in water, sodium hypochlorite or potassium hydroxide. Such reagents will soften tissues in order to facilitate its removal with the aid of tweezers. While maceration and manual dissection consume a large amount of time (especially in large animals), the use of flesh-eating bugs of the genus *Dermestes* might represent a valuable tool for osteology. Chemical preparation with sodium hydroxide was found to be the best method in terms of time required to complete the procedure, number of bones

recovered, color of the bones, and odor of the preparation. However, the chemical method has the disadvantage of dissolving and cracking the bones if the concentration used is high and prompt attention is not given to the preparation (Onwuama et al. 2012). Another method for analyzing bone structure is known as clearing and staining (Taylor and Van Dyke 1985), in which the specimen is subject to several stages and reagents in order to have its muscles and most tissues translucent, while bones are dyed red and cartilage dyed blue (Fig. 1). This method can be modified to stain simultaneously nerves (Song and Parenti 1995). However, all the aforementioned techniques are highly invasive, damaging all tissues and structures associated to bone. Recently, new techniques were developed to cope with the limitation posed by morphological studies of anatomy in live or rare specimens, such as computed tomography (Schaefer and Fernández 2009) or magnetic resonance. These techniques allow 3D images of hard tissues, and with proper staining techniques also low-density structures such as muscles and glands (Dickinson et al. 2018). They are particularly valuable in paleontological studies where fossils cannot be extracted from the matrix or to visualize internal structures of the fossils (Racicot 2017). More recent techniques such as the images from

synchrotron light source have proven to be a promising tool in virtual dissections at an impressive resolution of 30 nm (Lu et al. 2019). This resolution is able to provide data at a level similar to histological dissections in organisms.

Microscopic studies on organism morphology were only made possible with the origin of the microscope, in the seventeenth century. At that time, even though lenses that amplified vision already existed, they were not implemented in such a way as the microscope to visualize structures at a microscopic level. The earliest record of the existence of a microscope is from 1622, in a letter by Constantijn Huygens in London (Huygens 1622; Bardell 2004). However, the earliest records of microscopic observations date from 1625 and 1630 and are investigations of a bee and a weevil by Federico Cesi and Francesco Stelluti (Bardell 1983, 2004). After its invention, improvement of the microscope quality went by,

associated with quality of images assessed and greater magnification (Bardell 2004). The invention of the microscope allowed the investigation of parts of organisms, mostly by specific cuts of their organs, tissues and elements. It was in the nineteenth century that **histology** was then recognizable a discipline, with the concept of tissue being introduced by Bichat in 1801. As its definition, the field of histology aims to study the structures of tissues and organs of an organism. Also called microscopic anatomy for some, modern histology is not merely descriptive but also includes many aspects of molecular and cell biology in order to contribute on the cell organization and function (Pawlina 2016). Even though methods used for histological methods vary, much of the area deals with techniques that involve light microscopy (Fig. 2). Past studies have dealt with several methods involving electron microscope, but current studies usually

**Morphology, Fig. 2** Histology of different organs of wistar rat (a) kidney, (b) lung, and (c) spleen. Scale 50  $\mu$ m, 400  $\mu$ m, and 50  $\mu$ m, respectively. (Photos by Fernanda Paulini)

include atomic force microscopes that can provide images with much higher resolution (Pawlina 2016). Additionally, auxiliary techniques as histochemistry, cytochemistry, and immunocytochemistry allow visualization of different structures. The goal of histochemistry is to provide color and contrast to microscopic images by the use of techniques to accomplish the specific labeling of biological structures (Davis 2011). Comparably, cytochemistry involves specific reagents to identify biochemical content of cells. Finally, immunocytochemistry aims to anatomically visualize specific protein or antigen in specific cell spots by the use of primary antibodies under a fluorescence microscope (Pawlina 2016).

Not only histology was made possible with the origin of the microscope but also a few areas that are directly related to morphology studies. For instance, while histology deals with organismal tissues, **cytology** is the field that studies the structure and function of the cell. Also called cell biology, it focuses on studying the basic unit of life, in order to understand its its physiology, metabolism, life cycle, and chemical composition. As histology, cell biology directly contributes on understanding the morphology of an organism through its structure and function. The explosion of new imaging and computer technologies continues to provide fresh and spectacular views of the inner workings of living cells (Alberts et al. 2014). Finally, **Embryology** deals with the prenatal stage of animals by investigating the formation and development of the embryo and fetus. It is intrinsically linked with cell biology and histology, as these fields aid on the clarification of several developmental issues.

## Morphology and Evolution

Animal morphology has been slowly shaped over millions of years, and an understanding of evolutionary history can aid on the comprehension of patterns observed in living organisms. Anatomy evolves often through changes in developmental genes, but the causal mutations, and their effects, remain largely unknown (Frankel et al. 2011). Thus, understanding the phenotypic effect of

size and mode of action of genes that contribute to these complex traits is an important challenge for evolutionary biologists.

In general, rates of morphological evolution vary among different taxonomic groups, thus variations in rates of evolution has been proposed as one of the main drivers for the great diversity of organisms on Earth (Sherrat et al. 2017). The subarea of evolutionary biology focuses on the documentation of the variability of organisms in the tempo and evolution, identifying extrinsic and intrinsic factors pertaining to such variabilities, such as lineage biology, ecology, and development (Sherrat et al. 2017). Such goals are currently being assessed by recent methods as the phylogenetic comparative methods that include huge phenotypic datasets with an evolutionary purpose.

Additionally, an evolutionary insight into morphology can offer ways of understanding some human disorders and diseases. Understanding how a structure evolved, and how structures are linked during evolution and development can therefore shed light on why and how abnormalities arise.

## Morphology and Systematics

Classifying is probably an endeavor as old as our species. The activity of grouping certain living beings based on their attributes, and naming those groups is a powerful tool to convey information about them. Even before science as we know, the relevance to the survival or thriving of a community could depend on the ability to recognize certain attributes of organisms as an indication of danger or food. The placement of an organism to a group in detriment of another group was based on phenotypic characteristics, for the most part, its morphology. For this reason, the birth of biological classifications is hand in hand with the birth of comparative morphology.

The first attempt of a more thorough classification was by the Greek philosopher Aristotle. Aristotle's classification was followed by other ways to classify organisms, but the birth of the modern taxonomy and our still used scheme of

classification was proposed only in the eighteenth century by Carl Linnaeus. In his scheme of classification, the basic unit was the species, in which morphologically similar organisms would be grouped. To this species, a binomial name would be attributed. Similar species would be grouped in a given genus, and similar genera in a given family, and so forth. In this hierarchical scheme of classification, each of these taxonomic ranks (e.g., species, genera, family, and order) was arranged by degree of inclusiveness. The degree of morphological similarity among other taxa is determinant for placing the species in each of these taxonomical ranks. For Linnaeus, some classes of morphological characters were more important for a given taxonomical group than to others, as an example, his entire plant classification was based on the morphology of reproductive structures (Linnaeus 1753). The Linnean system of classification is so practical and simple, that is still used with few modifications, even though it was conceived in a distinct paradigm. In this paradigm, known as fixism, it was believed that each and all species were created exactly like what we see today.

In the nineteenth century, the understanding of the natural world was profoundly changed by the proposal of the theory of biological evolution (Darwin 1859). Breaking with fixism, Darwin proposed the evolutionary process as a branching tree of descents with modifications. This phylogenetic pattern gave the theoretical framework for the hierarchy of similarities observed by Linnaeus and which formed the basis for his classification. Linnaeus' observed morphological similarities used in the classification are now interpreted as the result of shared common ancestry. For Darwin, morphology is the path to understand evolution and "is the most interesting department of natural history and may be said to be its very soul" (Darwin 1859, p. 434).

One century later, Hennig (1966) proposed that not all similarities are equal. And that classifications should reflect the evolutionary history of the group and consequently, only similarities due to common exclusive ancestry should be considered. Similarities not reflecting this common ancestry, as convergences, should not be used. This

methodology, named by Hennig (1966) phylogenetic systematics and later known as cladistics, became quickly the paradigm in biological classification (Schuh and Brower 2009). In the following decades, many classifications were proposed based on this methodology with morphological characters, until molecular characters became increasingly more used in phylogenetic analysis.

However, at the end of the twentieth century and beginning of the twenty-first century, there was a heated debate on the utility of morphological data for biological classifications in face of the growth of the molecular data (Hillis 1987; Hillis and Wiens 2000). The discussion centered on if one dataset had an advantage per se over the other, and how congruent they were. While the molecular data could be much larger than the morphological data, it could be applied only to a small portion of the diversity, since museum specimens and fossils could only provide morphological information (Hillis 1987). Several authors at that time advocated a combined analysis using both molecular and morphological data as a way to provide an improved estimate for the phylogeny in question (Wiens 1998). However, in recent years new sequencing technologies were developed making available genomic-scale datasets easily and at low cost (Lee and Palci 2015). In this phylogenomic age, molecular datasets surpass the morphological datasets many folds. As a consequence, morphological information has been increasingly relegated to a secondary role in phylogenetic analysis, usually excluded from it altogether with a few key characters optimized and discussed in the topology generated solely by the molecular data (Mooi and Gill 2010; Giribet 2015). The reasoning for excluding morphological characters is that the putative huge asymmetry between both kinds of datasets causes the morphological data to contribute little, if at all, to the phylogenetic structure when in a combined analysis and that morphology is more prone to convergences (Giribet 2015; Lee and Palci 2015). However, it has been shown that even with a very asymmetric data matrix, the morphological dataset can still change the position of taxa in comparison with the analysis without the morphological characters (Wiens et al. 2010).

Furthermore, the use of morphological data in a combined analysis allows the inclusion of fossil taxa which are crucial to understanding diversification and lineage origin and extinction (Giribet 2015; Pyron 2015).

## Morris Water Maze

Buddhamas Pralle Kriengwatana  
University of St Andrews, St Andrews, Scotland

## History and Application

The Morris water maze is one of the most widely used methods for testing spatial learning and memory. Developed by Richard Morris at the University of St Andrews in the 1980s (Morris 1981, 1984), experiments using the Morris water maze have made vital contributions to theoretical and methodological advancements in behavioral neuroscience and animal cognition.

The logic behind the Morris water maze is simple: subjects are placed in a circular pool of opaque water and must swim in the pool until they find a small hidden platform submerged beneath the surface of the water that they can stand on. The Morris water maze was initially developed for use with rats, which are natural swimmers yet intrinsically motivated to find and stand on the hidden platform in order to get out of the water. In the

classic version of the Morris water maze, the position of the hidden platform is constant in relation to the visual cues outside of the maze (e.g., posters located on the wall), so subjects can find the approximate location of the hidden platform by using these cues. After several learning trials, normal subjects become faster at finding the hidden platform, both in terms of speed (latency) and the distance taken to reach and stand on the platform. Once subjects have learned the location of the hidden platform, they are able to find the platform from any of the designated start locations, which are often at the edge of the pool. In test trials, the platform is removed and the time spent in the different areas of the pool are measured, with the assumption that subjects that have learned the location of the platform will spend more time searching in the area where the platform once was (Morris 1981). Other behavioral measures, such as the proximity measure (i.e., the distance between the subject and hidden platform, calculated every second throughout a trial), have additionally been developed to assess a subject's spatial learning and memory in greater detail (see Pereira and Burwell 2015). Development of accurate methods to quantify performance in the maze is important to properly control for the influence of factors unrelated to spatial learning, such as a subject's inability to swim towards the platform, sex, species (i.e., rats versus mice), age, health, and stress levels (reviewed by Vorhees and Williams 2006). For instance, prelearning trials are often included at the start of the experiment: in these trials the platform is not hidden but elevated above the water and visible to subjects. This is so subjects learn that there is a platform somewhere in the pool and will try to find it in later trials when it is hidden beneath the surface of the water. The prelearning trials also allow experimenters to see whether a subject has difficulty swimming in the maze and exclude any subjects from the experiment if necessary.

In any trial, different strategies can be used to find the location of the hidden platform (Brandeis et al. 1989). Subjects can remember the sequence of movements required to reach the platform or learn to locate the platform based on a cue

(purposely or unintentionally) present in the pool or room. Both of these strategies are inflexible, however, and may be ineffective if subjects start their search from a different point in the maze. When a subject finds the platform by learning the position of the visual cues relative to each other, they are thought to be forming a mental map of their environment and employing a place learning strategy (also known as a spatial strategy), which is a flexible strategy that enables the subject to find the platform from any starting point in the maze. Place learning strategies rely heavily on a brain region called the hippocampus (e.g., Morris et al. 1982), although neural systems distributed throughout the brain are involved in spatial learning and memory in the Morris water maze (D’Hooge and De Deyn 2001).

Even though it was originally designed for rats, the Morris water maze is ideally suited for comparing spatial learning and memory in different animals because navigating efficiently through environments is a natural and important behavior for practically every animal. A few adjustments allows the Morris water maze to be used with mice (Vorhees and Williams 2006), and variants of the Morris water maze have already been successfully developed for humans and songbirds. Virtual simulations of the Morris water maze are used for testing humans (e.g., Astur et al. 2002), while a “dry version” of the Morris water maze is used for songbirds (Mayer et al. 2013). These studies involving both humans and songbirds show that, like rats and mice, the hippocampus plays a key role in supporting place learning strategies, which suggests that function of hippocampus for spatial learning and memory is conserved across animal taxa.

[Jeff Bitterman](#)

Morton Edward “Jeff” Bitterman (1921–2011) was an American comparative psychologist—in the most literal sense of the term! His research, which was focused on fundamental learning processes, was distinctive for the number of different species that he compared across a productive career that spanned almost 70 years. This comparative breadth served as the catalyst for many methodological and apparatus innovations that Dr. Bitterman developed for the field. He also served in academic and disciplinary leadership roles. For these methodological, empirical, and

theoretical contributions, Professor Bitterman was recognized with numerous awards and honors.

## Personal and Professional History

On January 19, 1921, the former Stella Weiss, wife of Harry Michael Bitterman, gave birth to a son in the same Brooklyn house where she herself had been born. The Bittermans, who had married in Brooklyn in 1917, named their only child Morton Edward—although he would be called “Jeff” throughout his life. Jeff’s father owned a fur business in the Garment District of New York City, whereas his mother was a practical nurse. As for young Bitterman, he planned to pursue a career as a lawyer. After high school, he enrolled in New York University with that goal; however, encounters with two assistant professors of psychology at NYU changed Bitterman’s career plans (Balsam 2012) and, ultimately, psychology’s understanding of animal learning. Jeff became interested in psychology through an introductory course taught by the behaviorist George Benjamin Vetter, who studied personality and social psychology. Bitterman’s love for animal psychology was sparked by University of Michigan-educated Theodore Christian Schneirla, whose detailed studies of the behavior of ants (particularly the army ants of Panama) resulted in dozens of published articles and a book (Schneirla and Topoff 1971). Bitterman earned his B.A. in psychology from NYU in 1941, followed by an M.A. from Columbia University in 1942. His research at Columbia in Professor Carl John Warden’s Laboratory of Comparative Psychology resulted in Jeff’s first publication (Bitterman and Warden 1943), a study of inhibitory effects of conditioning on the seizure behavior of white rats. (It is interesting that Vetter’s own graduate work at the University of Washington had also involved the study seizure behavior, albeit in humans with epilepsy.)

For his Ph.D., Bitterman traveled upstate to Cornell University. Balsam (2012) noted that Jeff conducted research there on Pavlovian conditioning in sheep and other animals at Cornell’s “Behavior Farm” (see also Kirk and Ramsden 2018), directed by Dr. Howard S. Liddell.

Professor Liddell was a psychobiologist who examined the relation between mental illness and the Pavlovian phenomenon of experimental neurosis. However, Bitterman’s Ph.D. research was conducted in a very different domain: His dissertation, *Studies in Visual Fatigue and Efficiency* (Bitterman 1945a) was directed by Dr. Thomas Arthur Ryan, who had himself earned the Ph.D. in psychology from Cornell 8 years earlier. Professor Ryan’s own research program was focused on real-world applications of psychology (e.g., Ryan 1947), so it is unsurprising that Bitterman’s topic was rather applied, involving a series of studies testing whether psychophysiological measures such as heart rate, squinting, and blink rate are valid and sensitive measures of eye fatigue during reading (see also Bitterman 1945b). These data were published a short time after a related note Bitterman authored in the *American Journal of Psychology*, in which he argued that fatigue could be objectively measured by the ratio of performance to expended effort (i.e., efficiency; Bitterman 1944). By the end of 1946, five other related articles authored by Bitterman had appeared in the literature (Bitterman 1945b, 1946a, b; Bitterman and Soloway 1946a, b). Within another year, Dr. Bitterman had a total of 21 publications, and others forthcoming, to his credit, including collaborations with Cornell Professor Dr. Frederick Lawrence Marcuse on psychophysiological indicators of posthypnotic amnesia (Bitterman and Marcuse 1945) or of guilt or innocence (e.g., Bitterman and Marcuse 1947), and a classroom demonstration (Marcuse and Bitterman 1944). Dr. Marcuse (1940) had earned his Ph.D. in 1940 from Queen’s University with a dissertation titled *A Study of Abnormal Behavior in the White Rat*, so it is easy to imagine that the two scientists might have found common research interests to discuss beyond the topics they published collaboratively.

With this early record of scholarly output, Dr. Bitterman was offered employment by Cornell University in 1945. He served on the psychology faculty until 1950, before being recruited to the University of Texas in Austin by Professor Karl M. Dallenbach, himself a Cornell Ph.D. recipient (1913) and a professor of Bitterman’s, who in 1948 had moved after 30 years on Cornell’s

faculty to become chair of the psychology department at Texas. Bitterman joined the faculty as an associate professor. He was also named co-editor (1955–1973) of the *American Journal of Psychology*, which Dallenbach had purchased from G. Stanley Hall in 1921 (see Evans 1987). Dallenbach served as a lifelong mentor to Bitterman, and the two remained very close until Dallenbach's death in 1971. Dr. Bitterman served on the psychology faculty at Texas from 1950 to 1955, followed by 2 years (1955 to 1957) at the Institute for Advanced Study at Princeton, NJ. The Institute was directed by Dr. J. Robert Oppenheimer, the famed physicist. In a letter recommending Bitterman for a NATO Fellowship, Oppenheimer described Jeff as “an unusually imaginative, fertile, active and clear headed psychologist, with a long record of good work done” and a “most agreeable scholar, clear, humorous, and with wide interests” (Oppenheimer, unpublished letter of recommendation, January 23, 1956). In 1957, he moved to Bryn Mawr College to become the department chairperson at the rank of associate professor. Bitterman was promoted to the rank of professor in 1961. He remained at Bryn Mawr until 1970, and then had a brief stint on the faculty of the University of South Florida (1970–1971). In 1971, Georg von Békésy recruited Professor Bitterman to the University of Hawai'i at Mānoa (Balsam 2012). von Békésy, who had been awarded the Nobel Prize in Medicine in 1961 for discovering the function of the cochlea in mammals, valued Bitterman's expertise in animal behavior to complement ongoing work at Békésy's Laboratory of sensory sciences. This research unit would later merge into the Pacific Biosciences Research Center and become known as the Békésy Laboratory of Neurobiology, for which Bitterman served as Director beginning in 1990. Dr. Bitterman retired and became an emeritus professor at the University of Hawaii in 2001.

Ten years into an active retirement from academic duties—he published at least 10 articles after 2001—Dr. M. E. Bitterman died on May 10, 2011 in San Francisco, CA. He is survived by his wife of nearly 44 years, Mary Gayle Foley Bitterman, three daughters (Joan, Ann, and Sarah

Fleming), and two grandchildren. Jeff's first marriage to Shirley Subke, mother of his two older daughters, ended in divorce. With Hawaii and California being his two residences for many years, his ashes were scattered in the Pacific Ocean (M.G.F. Bitterman, personal communication, August 23, 2020)

## Professional Contributions

Jeff Bitterman was a creative and tireless researcher and a prolific writer. Ten years after earning his Ph.D., Bitterman had already published 74 empirical papers, reviews, replies, and other works. His 1960 article, *Toward a comparative psychology of learning* (Bitterman 1960) was a classic in our field. He first challenged the field to be truly comparative: Updating the famous critique of Beach (1950) that psychology too exclusively studied rats and pigeons, to the exclusion of other animals, Bitterman wrote that “It is our willingness to *assume* that the process of learning is essentially the same in all animals which has been responsible in large measure for our concentration on the rat” (pg. 704, emphasis his). Rather than being a field built on assumption, Bitterman argued that comparative psychology should be true to its name and determine empirically whether the similarities (and differences) across species are merely superficial. He wrote, “The resemblances may, in fact, be more than superficial, but we shall never know until our level of inquiry becomes more than superficial” (pg. 705). Bitterman illustrated this willingness to study learning in a truly comparative way by discussing his own research with human adults and children, rats, fish, crabs, blowflies, and earthworms. To be sure, research with such a wide range of species presents methodological challenges seldom faced by the scientist studying learning by pigeons, rats, and monkeys. Accordingly, Bitterman (1960) described apparatus innovations for studies of these atypical animal species—just a few of the creative methodological contributions that characterized his remarkable career (e.g., Couvillon et al. 2003; Horner et al. 1961; Longo and Bitterman 1959, 1963; Pert and

Bitterman 1969; Potts and Bitterman 1968; Woodard and Bitterman, 1974).

Bitterman (1960) further described two broad (and complementary) strategies for comparative psychology. The first, and most common, follows the tradition of Yerkes, Harlow, and many other scholars who develop a particular standardized test, administer the assessment to multiple species, and then rank or otherwise compare the animals in terms of performance on the measure. The second, described favorably by Bitterman, involves the study of multiple species not by comparing performance on a particular test or apparatus, but rather by extensive investigation of the principles of learning of each species “as an attempt to determine whether learning in different animals may be understood in terms of the same set of laws or whether different laws are required” (pg. 707). Arguably, no comparative psychologist in history has better illustrated this second strategy of inquiry than Dr. M. E. Bitterman.

It is impossible to provide a comprehensive review of all of Bitterman’s research publications, but several other key contributions merit particular attention for the impact they had on the field and the ways that they illustrate chapters of Jeff’s scholarly interest. Bitterman (1965) investigated manipulations of hunger in spatial and habit reversal learning by rats and fish, not comparing absolute performance itself across species, but rather the functional models of the relation between hunger and learning by the two species. The primary distinction between rats and fish, according to this review, was that rats demonstrated progressive improvement in tasks such as habit reversal (whereas fish failed to demonstrate this tendency) and fish showed random matching in probability learning trials (a response pattern demonstrated by decorticated but not typical rats). Bitterman then extrapolated these findings to monkeys, pigeons, turtles, cockroaches, and earthworms. This paper has been highly cited, contributing to later comparative work (e.g., Cambraia 2019; Cauchoix et al. 2017; Bobrowicz 2019).

In 1975, Professor Bitterman again called out comparative psychology, criticizing its lack of theoretical foundation (Bitterman 1975). He

suggested that this deficiency was due to the failure of animal psychologists to explore evolutionary theories of learning, and to the overgeneralized acceptance of Pavlov’s and Thorndike’s work in comparing animal learning. As in his earlier critiques, Bitterman observed that there is a common assumption that all animals follow the same law of learning. Thus, two views contrast with regard to animal learning: the view stemming from Thorndike and Pavlov suggesting that learning among animals is fairly universal, and the second view related to ethology, treating animal learning as ecological specializations specific to each organism and its niche. Bitterman provided empirical examples to illustrate the significant differences between diverse animals, and echoed his earlier views on the ideal strategy for comparative psychology (i.e., by seeking to answer the question, “Can the performance of multiple species of animals be described by a common set of psychological principles?”). This frequently cited *Science* publication continues to be discussed as important for setting a research agenda for comparative psychology (e.g., Cabrera et al. 2019; Muszynski and Couvillon 2020).

Contemporary comparative psychologists probably best remember Professor Bitterman for the innovative studies that characterized the most recent chapter of his incredible research career: investigations of learning by honeybees (e.g., Bitterman 1976, 1983, 1996; Cooke et al. 2007; Couvillon and Bitterman 1980). His systematic studies, using paradigms from Pavlovian conditioning, habituation, discrimination learning, spatial learning and memory, and symbolic matching, established that bees demonstrate many similarities with vertebrates with regard to behavior and performance. For example, in terms of parameters of reward, honeybees demonstrated similar patterns of incentive contrasts that have been reported in studies with rats and opossums. Across publications, this research (much of it conducted with collaborator Patricia Couvillon) is impressive not only for the patterns of behavior demonstrated by the bees, but also for the number of standard comparative psychology testing paradigms, developed for vertebrates, that were

successfully employed with the insects. For all of these reasons, the honeybee publications are among Dr. Bitterman's most impactful, and continue to be extensively cited by other scientists who study bee behavior (e.g., Dawson et al. 2016; Daniel 2020; Muszynski and Couvillon 2020; see also Macphail 1987).

Across his career, Professor Bitterman generated over 300 publications in scholarly literature. This work attracted grant funding from the Office of Naval Research, the National Institutes of Health, and the National Science Foundation. For his contributions to psychological science, Dr. Bitterman was recognized with numerous honors, including fellow status in the American Association for the Advancement of Science and the American Psychological Association (APA), the latter of which recognized Bitterman with the D. O. Hebb Distinguished Scientific Contribution Award (2001, from APA Division 6) and the Ernest R. Hilgard Award for Lifetime Career Contribution to General Psychology (2004, from APA Division 1); membership in the Society of Experimental Psychologists, which awarded Bitterman their Howard Crosby Warren Medal (1997); the Humboldt Prize from the Federal Republic of Germany (1981); and the Regents' Medal for Excellence in Research from the University of Hawaii (1992). Across his career, Professor Bitterman was awarded more than 30 visiting professorships and research positions, including by the University of California at Berkeley, Princeton U., U. Pennsylvania, the Bermuda Biological Station, the Lerner Marine Laboratory, Naples Zoological Station (Italy), Moscow University and the Sechenov Institute of Evolutionary Morphology (USSR/Russia), U. Michigan, U. Brasila (Brazil), Campeche Biological Station (Mexico), U. California at Davis, U. Dusseldorf, Weizmann Institute of Science (Israel), Simon Fraser U. (-Canada), U. Freiburg and U. Frankfurt (Germany), U. Sydney and the Edward River Crocodile Station (Australia), Brain Research Institute (Yugoslavia), Georgetown U. School of Medicine, U. Auckland (New Zealand), and other universities in Japan, Spain, and Germany. Dr. Bitterman held Fulbright Professorships in Argentina and Germany and Humboldt Research

Fellowships in Germany. In addition to his long service as co-editor of the *American Journal of Psychology*, Bitterman was appointed to the editorial boards of the *Journal of Comparative Psychology*, *Animal Learning and Behavior*, *Psychonomic Science*, and *Behavior Research Methods, Instruments and Computers*. In these and similar roles, his expertise, insight, unyielding standards, and candor served to promote the rigor, sharpen the arguments, and challenge the assumptions of the field of comparative psychology.

Professor Bitterman also contributed to the field through his mentorship of students and collaborators. Some of the most important scholars in the field of comparative psychology have benefited from the opportunity to work with and learn from Jeff. For example, Dr. William Roberts, who earned master's (1962) and doctoral (1965) degrees under Bitterman's direction, described his advisor as a brilliant scientist and a charming man, but someone who did not suffer fools gladly—and who defined fools broadly (W. Roberts, personal communication, August 6, 2020). The razor-sharp intellect that kept Bitterman's research on the cutting edge of science could also lead to harsh and cutting criticism of others' work. Dr. Mauricio Papini, who was strongly influenced by Bitterman's published work (particularly the 1960 paper discussed above), communicated with Jeff for years and received fellowships to work with him. Dr. Papini remembered that Bitterman treated his advisees more like colleagues. For example, when Papini worked in Bitterman's lab, the senior scholar would ask Papini what his vision for certain experiments was. Papini explained, "the work we were doing in Hawaii was brand new, so we had to design the lab from scratch. I had a lot of freedom with the design" (M. Papini, personal communication, August 8, 2020). Reflecting also on Dr. Bitterman's capacity for incisive criticism, Dr. Papini notes that, to this day, he asks himself "What would Jeff say about this?" whenever he writes something speculative.

Professor M. E. Bitterman was a giant in the study of animal behavior. His scholarly interests and contributions spanned the animal kingdom, including arthropods and nonarthropod

invertebrates, crustaceans, fish, birds, and a wide range of mammals including human children and adults, and his methodological innovations served as catalysts and heuristic inspiration for the contributions of other scholars. If comparative psychology is to be truly comparative, and to produce a science of animal (versus of “some animals”) behavior, then Bitterman provided both the theoretical foundation and also an enduring example of how the discipline should proceed.

## Mosaic Cognition

Vincent Barnett

Independent Scholar, London, UK

## Synonyms

Modular cognition; Mosaic brain; Mosaic evolution

## Definition

Mosaic cognition refers to the fact that the mammalian brain is composed of various functionally separate morphological systems which have evolved, in part at least, by means of processes of mosaic evolution (modular evolution) or selective evolutionary changes on individual parts of the brain that were (in some degree at least) developmentally and historically distinct.

## Introduction

It has been outlined that modularity (or a mosaic design) is found at every level of an organism's structure, including the brain, although anatomical and functional modularity should clearly be distinguished from each other, as they by no means always coincide. In addition, brain modularity exists in tandem with the tailored functional and developmental integration of brain structures, as modules link with other local (and even some remote) modules at various hierarchical levels of connectivity (Lieberman 2011). Perhaps the most basic modular distinction in any primate brain is that between the left and right hemispheres, which are in many ways functionally specialized (or lateralized).

It has been suggested that these two features of organisms taken together – brain modularity and the localized integration of these modules – contribute to the emergent property of covariant evolvability, as the flexible and independent nature of a modular system facilitates many

## Mosaic Brain

### ► Mosaic Cognition

small transformations over time, leading to the prevalence of so-called evolutionary tinkering. This evolvability feature is especially prominent in relation to the high degree of complexity of many brain structures, although it is debatable whether evolvability and modularity are capacities that are directly selected for. But, as distinct from the functional modules themselves, how exactly does mosaic evolution progress as a process?

## Mosaic Evolution

As has been explained about mosaic evolution, “brain structures with major anatomical and functional links evolved together independently of evolutionary change in other structures” (Barton and Harvey 2000, p. 1055), and evolution in these sub-structures also involves dynamic interrelationships among different brain components, this being a type of functionally independent mosaic progression. For example, the size of the neocortex – the largest and most recently evolved part of the cerebral cortex – shows a fivefold difference comparing primates and insectivores (insect-eating animals), even after scaling with the rest of the brain.

Mosaic evolution also involves various social and ecological (or environmental) factors that have different effects across distinct cognitive domains and in different periods of time, with cladistic branching patterns of evolutionary development being the result. These ecological contexts all vary both spatially and temporally. Mosaic evolution is the opposite of concerted or coordinated evolution, in which an individual part is evolved in correlation with the evolution of the whole of the structure that is involved.

## History of the Term

One of the earliest uses of the term “mosaic evolution” was in the field of paleontology, in relation to the well-known so-called missing link (or transitory form) of *Archaeopteryx*

*lithographica*. Charles Darwin had originally called the *Archaeopteryx* “that strange bird” (Darwin 1872 [1859], p. 284), while elsewhere it was labelled as a “misbegotten-bird-creature”: now it is regarded as the very first known bird. While the paleontologist Richard Owen had noted the “enigmatic character” of *Archaeopteryx* (Owen 1863, p. 44), he declared it unequivocally to be a bird soon after the first fossil of it was discovered in 1861. It is now known that birds are small flying theropod dinosaurs, but because of Owen’s skepticism about the overall theory of evolution, he downplayed the transitional significance of *Archaeopteryx*.

T.H. Huxley was the first commentator to use what he elsewhere called “comparative zoological reasoning” in order to explicitly highlight the intermediate nature of the skeletal form of *Archaeopteryx* (Huxley 1863, p. 85). In addition, Huxley compared *Compsognathus longipes*, a chicken-sized bipedal meat-eating theropod (another birdlike dinosaur), to *Archaeopteryx* as a dinosaur-bird intermediary, the two animals having some definite structural similarities/evolutionary homologies. As has been explained on this topic, nearly a full century later:

De Beer (1954) studied the five known [fossil] specimens and pronounced *Archaeopteryx* to be an example of what he termed “mosaic evolution.” In De Beer’s view, *Archaeopteryx* is an anatomical mosaic because it presents a mixture of character states that are (1) “reptilian” (e.g., it has teeth and a bony tail), (2) intermediate between reptilian and birdlike (e.g., its weakly developed sternum), and (3) fully birdlike (e.g., it possesses feathers). (Eldredge 1989, p. 49)

Sometime later, the mosaic evolution concept was further applied to the mandible of *Archaeopteryx*, which was also seen to have both reptilian and avian characteristics (Cracraft 1970). Here the term “mosaic evolution” is being used to refer to an anatomical mosaic of physical features that had their evolutionary origins in multiple animal taxa. The concept then became popular within the field of macroevolution as specifying independent evolutionary change of various portions of the phenotype (Stanley 1979).

## Variant Meanings

More recently, various different variant meanings of the mosaic evolution concept have been articulated, for example, as follows: (1) morphological instability in a certain phase of a branched phylogeny, or the staggered evolution of a mosaic of different ancestral and descendent characteristics; (2) multiple trajectories of the same trait in a branched phylogeny, or the same trait appearing in different species over time; and (3) a trait itself as a mosaic of sub-traits, or a combination of different functional elements (Parravicina and Pievani 2019). Meaning number one is by far the most common in the literature but the other two meanings sometimes appear as elements of wider analyses.

Elsewhere, mosaic evolution has been defined somewhat differently as “the evolution of different components of a phenotype at highly unequal rates” (Lock and Peters 1996, p. 372), a conception that can here be termed temporal mosaic evolution. A related concept of modular evolution has been outlined, in which selection mechanisms act on each carrier of modular-contained information at various levels of biological organization and complexity (Vinicius 2010). Finally, evolutionary change in one body part without any simultaneous changes in other body parts is a simpler definition that is sometimes encountered. These are all variants on what might be termed the functionally independent morphology concept, given previously as mosaic evolution meaning number one.

It has correctly been pointed out that mosaic and concerted evolution are not mutually exclusive, as both can occur in relation to different physical features (D’Aniello et al. 2019), similar to how domain-specific and domain-general cognitive mechanisms are also not mutually exclusive. In addition to considering the brain of *Homo sapiens*, there are various different neuroanatomical components and structures that are found across different animal species; for example, mammalian brains are composed of some different components to those of birds (van Horik et al. 2012). This latter point leads neatly into a consideration of mosaic brain evolution, rather than the more general concept of mosaic evolution.

## Mosaic Brain Evolution

Mosaic brain evolution is simply mosaic evolution applied to the various regions of the brain, which has been categorized as “the most modular part of the body” (Lieberman 2011, p. 183). One of the first researchers to implicitly identify temporal sequences or “successive waves of circumferential differentiation” in brain evolution was Raymond Dart, who identified subdivisions in the reptilian brain such as the oldest identifiable neocortex (Dart 1934). This then led to the idea developed by Paul MacLean of the so-called triune human brain, with three separate evolutionary layers: (1) the reptilian or primal brain (brain stem and midbrain); (2) the paleo-mammalian or emotional brain (limbic system); and (3) the neo-mammalian or rational brain (neocortex), although this is now known to be a significant oversimplification of *Homo* brain structure (Ploog 1971).

One of the first researchers to explicitly apply the mosaic evolution concept to the brain was Ralph Holloway, who investigated the evolution of hominid brain size and how this could be measured in relation to “interpretations of time-related shifts in the nature of hominid mosaic evolution” (Holloway and Post 1982, p. 73). Holloway concluded that neuronal structural reorganizations and brain size increases likely involved each other and/or occurred in tandem, implying that mosaic cognition had both overall volume and specific component features.

As has been explained, the contemporary hypothesis of mosaic brain evolution involves selective forces acting on specific regions of the brain, whose adaptive reactions do not then involve other parts of the brain (D’Aniello et al. 2019). Correspondingly, individual elements of the brain are grouped within structurally and functionally separated neural systems that are devoted to particular cognitive tasks. For example, as has been outlined regarding the neural generation of emotion: “emotions can be decomposed into more basic psychological processes that correspond to large-scale networks in the brain” (Fugate et al. 2014, p. 44). Taken as a whole, these neural networks constitute a set of reference areas for particular emotions.

Specific to this is a hypothesized principle of proper mass: the mass of neural tissue controlling a particular cognitive function is appropriate to the amount of information processing involved in performing that function (Falk 2002). It has been concluded about the processes influencing brain enlargement that “primate brain structure is largely driven by selection on sensory and cognitive specializations that develop in response to divergent sociological niches” (DeCasien and Higham 2019). Correspondingly, different primate brain components have altered their size to varying extents, at varying times and in varying ways in relation to these niches (Barton 2007). In addition, selection processes can act on various different features of the brain: the number of neurons as illustrated by overall brain size and surface structural convolutions, and then the level of connectivity of neurons and the corresponding connection patterns (Stone 2007), this mirroring Holloway’s previously articulated distinction between volume and component.

Of course, just because that human brain is divided into numerous separate systems, does not mean – in and of itself – that mosaic evolution rather than concerted evolution was the dominant force at work in its recent evolutionary phases. However, there is some good evidence that mosaic evolution was indeed a force in operation to a significant degree. For example, one study on patterns of brain covariation (correlated variation) in chimpanzees and humans concluded that both types of brain had modular structures and that spatially adjacent regions in both types of brain covaried much more than spatially separated regions (Gomez-Robles et al. 2014).

Another study of the avian cranium concluded that it was highly modular, with the presence of seven independently evolved anatomical regions (Felice and Goswami 2018), while a study of a series of primate brains concluded that corresponding brain regions were expanded in correlation with both diet quality and either nocturnal or diurnal behavioral needs (DeCasien and Higham 2019). In general, the existence of some degree of mosaic brain evolution is now commonly accepted in the literature on cognition, although this does not mean that concerted

evolution of some closely interconnected brain systems has never occurred. In the case of primate brains, a mosaic of neurological systems is most extensively developed within the cerebral cortex.

## The Cerebral Cortex

A key evolutionary development in the higher primates was a large increase in the size of the cerebral cortex (the outer surfaces of the two cerebral hemispheres) and the underlying thalamus; in *Homo sapiens*, the cerebral cortex is 76% of brain weight and about 0.23 m<sup>2</sup> in area, whereas in the gorilla it is only 68% of brain weight (Holloway 2000). The cerebral cortex is composed mostly of neocortex, the overall size of which in primates has been shown as coevolving with group size and language use (Dunbar 1993) and which is found only in mammals.

Neocortex has its own distinct six-layered structure and numerous layer-specific connections, and it is divided into three basic parts: sensory, motor, and association areas, with numerous mosaic subdivisions. As has been explained, the *Homo sapiens* cerebral cortex contains relatively more parietal and temporal lobe association cortex compared to other primate species, this association cortex facilitating complex intermodal cognitive functioning (Holloway 2000).

Consequently, the cerebral cortex plays a central role in various different aspects of *Homo* cognition, including many of the complex abilities that have reached their apogee in *Homo sapiens* such as communication skills, tool manipulation, and abstract thought processes; hence its evolution was closely linked to the development of the higher *Homo* cognitive functions. The neocortex plus the basal ganglia is sometimes called the executive brain (Stone 2007). The thalamus operates as the communicative sensory gateway to the cerebral cortex for subcortical regions of the brain.

The cerebral cortex as a large collection of neural circuitry is perhaps the most significant brain feature that separates *Homo sapiens* from the earliest *Australopithecines*. In terms of the forces that may have driven its mosaic evolution,

various different hypotheses have been advanced in the literature as explanations. The most commonly encountered are the Machiavellian intelligence hypothesis (social manipulation abilities), the technical intelligence hypothesis (tool/shelter construction abilities), the social intelligence hypothesis (group living abilities), and the cognitive buffer hypothesis (insurance against environmental variation), but some staggered combination of them is another definite possibility. Social transmission intelligence as a specialized behavioral adaptation has been directly linked to mosaic brain evolution, but behavioral flexibility and problem-solving ability can also be so linked (Brown 2008; Vonk 2016).

## Mosaic Cognition

So far the implicit assumption has been made that mosaic brain evolution is synonymous with “mosaic cognition” – which is the actual title of this entry – but might it not actually be so? Mosaic cognition – the existence of numerous functionally separate neurological systems – has (in an important sense) been generated by mosaic brain evolution, and hence it is morphologically and evolutionarily inseparable from it. However in perceptual terms, the fact that cognition takes place across a mosaic of different neural systems could have important consequences for how it operates in performance and reliability terms.

In reality, “perception” is much more accurately described as a series of separate and neurologically distinct perception processes – the modularity of perception – and this fact needs always to be kept in view. The nature of mosaic cognition means that there must also be specific neural systems devoted to combining different types of perception-derived information (as a form of meta-cognitive synthesis) when this is required for additional computational or behavioral reasons. This is a particular type of meta-cognitive processing and regulation and may involve the functioning of several hierarchically organized interlinking neural networks (Smith et al. 2018; Gibson 1990).

For example, auditory and visual perceptions are often employed in tandem: when finding the precise source of a sound in a visual field by listening for the direction of the sound and checking for other visual clues to its origin for instance. In turn this means that the possibility of generating meta-cognitive errors may exist through these types of combinations, at least in some instances. Individual perception systems are also subject to various types of processing distortions and perceptual illusions, as the central nervous system sometimes makes educated guesses using only partial data plus a degree of extrapolation. In these senses, mosaic cognition can be employed as a general term that refers to various types of meta-cognitive combinations of the inputs from individual neurological and perceptual systems.

## Conclusion

In this entry, three distinct but related concepts of mosaic evolution, mosaic brain evolution, and mosaic cognition have been presented in outline, and some of their connections have been traced. The link to wider anatomical modularity and localized functional integration patterns has also been briefly considered. However, there is a wider sense in which all living organisms are constituted from mosaic morphological systems. As has been explained in this respect:

The fact that genes influence and are influenced by behavior is exactly what an evolutionary psychologist would expect if information-processing bundles are the products of a mosaic evolution at different levels (genes, cells, neurons, structure, cognitive mechanisms, and outward behavior) . . . [all] organisms are not necessarily cohesive wholes but rather bundles of interests with common and conflicting goals. These bundles are subject to selection and include catalytic reactions, biochemical cascades, neuronal firing, structural components, neuro-cognitive activation, behavior, and learning (individual to social). (Brown 2008, pp. 130–131)

Multilevel mosaic evolution is, therefore, a new meta-level concept that arises out of the fact that in the development of such organic bundles of interests, mosaic cognition is one

expression of the various different types of mosaic evolutionary change.

## Mosaics

Hendrik de Buhr  
ETH Zurich, Zurich, Switzerland

## Synonyms

### Mosaicism

## Definition

Mosaics describe a mixture of two or more cell populations with different genotypes in one individual.

## Introduction

Mosaics were discovered by German-born American geneticist Curt Jacob Stern in the early 1930s showing that genetic recombination not only happens during meiosis but can also take place during mitosis resulting in somatic (body) mosaics containing genetically distinct types of tissue (Stern and Sekiguti 1931; Stern 1936). The term “somatic mosaicism” was later coined in the 1950s by C. W. Cotterman.

## Genesis of Mosaics

Genetic mosaicism can derive through different mechanisms like anaphase lag (failed connection

of chromosomes (meiosis) or chromatids (mitosis) to the spindle apparatus), chromosome nondisjunction (improper segregation of homologous chromosomes or sister chromatids), endoreplication (replication of nuclear genome in the absence of cell division), and mutation in one cell during development (mutation only passed on to daughter cells) (Fitzgerald et al. 1979). Chimerism is often mistaken as genetic mosaicism, where two different genotypes arise during early embryonic development by fusion of more than one fertilized zygote resulting in two or more genotypes (which is similar to mosaicism). Mosaicism can be divided into somatic or germline/gonadal (restricted to gametes) mosaicism. Both can be individually present or occurring at the same time.

## Somatic Mosaicism

Somatic mosaicism describes somatic cells with more than one genotype most commonly arisen through mitotic errors from a single fertilized egg cell. They are prevalent in early and late phases of (human) life and underlie various mechanisms. Mitotic recombination or somatic crossover are basic mechanisms for mosaic tissue. Somatic mosaicism is common in embryogenesis through retrotransposition (position change of DNA sequence within a genome creating or reversing mutations) as undifferentiated cells contain long stretches of unmethylated genomic regions and are therefore more susceptible to transposable elements (De 2011). There are further endogenous and exogenous factors contributing to somatic mosaicism like DNA polymerase slippage and unbalanced chromosomal segregation (endogenous) or UV radiation and nicotine (exogenous). In addition, increasing DNA damage and DNA copy errors through life naturally increase mosaicism and therefore could lead to cancer development. Somatic mosaicism is also commonly found in cells underlying chromosome abnormalities like trisomies or Turner’s syndrome (around 30% of cases show mosaicism). Although most cases of trisomy develop during meiosis, there are mitotic cases through nondisjunction with occurrence in only a few cells with a loss of a

chromosome in these trisomic cells. Consequently, these patients, for example, with Klinefelter syndrome (46/47 XY/XXY mosaic), with some XY cells containing the normal number of 46 chromosomes and some containing XXY and 47 chromosomes show a milder phenotype than people with full trisomy (Strachan and Read 1999). Rever- tant somatic mosaicism as an opposite is a rare nondeleterious mitotic recombination event leading to a spontaneous correction of the mutant.

## Germline Mosaicism

Germline mosaicism or gonadal mosaicism occurs when more than one genotype is found specifically in gametes. This can derive from a mutation arising after conception (Orva and Orva 1998) or through epigenetic DNA methylation (Laurentino et al. 2014). Germline mosaicism can lead to hereditary carriers of diseases which show no phenotype themselves. Gametes are difficult to obtain and in pure germline mosaicism the somatic cells should not contain the mosaicism which makes diagnosis troublesome for genetic counselling. Various diseases are reexamined for hereditary germline mosaicism as disease onset was often mistaken for being induced through *de novo* mutations (Armaroli et al. 2015). As the nature of mutations is sporadic the frequency of germline mosaicism is not known, although higher occurrence is given with earlier mutation during development.

## Experimental Biology

Mosaics allow for multifold purposes in biological research. They can be intentionally created in a variety of model organisms and are powerful tools for studies of biological systems. Naturally, mosaics are valuable for experimentation in gene studies during early development (transplantation from blastula stage embryo into another one with different genotype) to obtain adult organisms with given perturbations. In addition, genes can be examined for tissue specificity, requirement for specific cell types, and cell autonomy

(if unaffected cells do take on the specific phenotype through environment differentiation).

Mosaics are commonly created in the model organism of the fruit fly (*Drosophila melanogaster*) through mitotic recombination originally induced through irradiation. The resulting DNA strand break could result in homozygosity for one of the two alleles leading to mutant cell clones after replication rounds. Modern methods incorporate transgenes selectively through Flip Recombinase (FLP) which recognizes Flip Recombinase Target (FRT) sites and allows recombination between them. CRISPR/Cas9 as a state-of-the-art system for gene editing creates mosaic mutations as an unwanted side effect with its underlying mechanism still elusive. Recent studies from Abyzov et al. (2012), for example, in induced pluripotent stem cells (iPS cells) show in addition that somatic mosaicism happens frequently and that the cells of origin for reprogramming (e.g., skin cells) show mosaicism as well, leading to differences between iPS cells and cells of origin (due to differences in fractions of cells).

## Conclusion

Mosaics consist of two or more cell populations with different genotypes in one individual. The underlying mechanisms are manifold and can be endogenous or exogenous and occurrence can be in germline cells (gametes) or somatic cells or both. Mosaicism can be undetected, have mild implications, or lead to disease phenotypes. In addition, mosaics are commonly used in experimental biology for studies of genes in model organisms or whole biological systems.

## Motivation

Germán Gutiérrez

Department of Psychology, National University of Colombia, Bogota, Colombia

## Causality and Motivation: What Moves Behavior?

Motivation is a construct that refers to the underlying causes of behavior. These causes have been analyzed as mechanisms that explain how behavior is controlled and changes, and the survival and reproductive advantages of behavior. Motivation

is often understood as a state that controls behavior. It is temporary and may be variable and reversible. This is one of the central aspects of the construct, as it accounts for the immense variation there is in the direction and scale level in all the different dimensions of behavior among individuals.

Niko Tinbergen (1963) proposed four questions to address the causes of behavior at these two levels: proximate and ultimate. These questions refer to mechanistic, developmental, functional, and phylogenetic causes and continue to be a useful guide in understanding the different types of factors that explain behavior.

Much of psychology literature has centered on proximate causes of behavior, describing in great detail physiological, developmental, cognitive, and social phenomena, associated with motivation. Psychology and other social sciences have placed a great emphasis on how changes in the environment affect our behavior, and how behavior changes over the lifespan of individuals, leaving the study of ultimate causes of behavior mostly unexplored. Similarly, evolutionary theorists emphasize ultimate causes and often ignore proximate causes of behavior that explain mechanisms common to different species. An approach integrating proximate and ultimate causes is very important for a clear and complete understanding of behavior (Wong 2000). An integrative, as opposed to a reductionist approach is more likely to cross-fertilize any discipline in this time of high specialization.

Motivation is inferred from behavior as it cannot be directly observed. This means that different measures may be used as indicators of motivation. For example, choice, magnitude, latency, frequency, and duration of response are all measures that have been used to determine the level of motivation of an individual. No single unit of behavior can be used as a general measure of motivation, as the response quality and structure (i.e., sequence and topography) may vary across different behavioral systems.

Motivational systems can be regulatory or non-regulatory. Regulatory systems are based on homeostatic mechanisms and usually control life processes such as feeding, thirst, and temperature

regulation. Most of the literature on motivational factors of behavior has mainly considered the feeding system. As feeding is a regulatory system, some methodological problems may appear when motivational mechanisms are to be studied. For instance, in order to study motivation, we often use an instrumental paradigm; under those conditions, changes in the balance of calories, fat, glucose, or water are induced by the experimenter, and, through its behavior, the subject is able to restore that balance. Deprivation must be carefully planned if a stable and motivated response is to be obtained without the subject's health being put at risk. In addition, any measure of behavior must be carefully planned in order to properly evaluate the motivational value of the stimulus, because as the subject becomes satiated there is change in the value of food, as well as the value of any stimulus associated with it. This issue, however, is not limited to regulatory systems and constitutes a challenge in any motivational study.

Nonregulatory systems are not vital in maintaining homeostatic levels of nourishment, excretion, or systems maintenance but can be powerful sources of motivational control of behavior and are also essential for the individual's fitness: survival and reproduction. For instance, sexual behavior is nonregulatory, yet it is one of the most powerful sources of motivation for species that reproduce sexually. Similarly, defensive behavior is nonregulatory but it is crucial for survival, and consequently, a powerful source of motivation.

Historically, motivational concepts such as instinct and drive have received much attention and have been used to explain the source of forces that account for the magnitude, timing, and direction of behavior. Those concepts resulted in controversies derived from theoretical approaches with differential emphasis on nomothetic vs. idiographic explanations, mechanistic vs. cognitive approaches, innate vs. learned behavior, and external vs. internal influences.

Instinct refers to an organized behavioral pattern, common to the members of a species, and independent of learning and experience. The concept was very popular early in the twentieth century as an explanation for behavior that was not

clearly explained by environmental influences. Konrad Lorenz and Niko Tinbergen developed models of motivation based on the concept of *fixed action pattern*, a development of the idea of instinct. These models, however, were not supported by behavioral and physiological evidence and are not currently driving research in the study of animal behavior, despite their usefulness for the development of behavior theory during the twentieth century (Burghardt and Bowers 2017).

The concept of instinct was the subject of controversy between ethologists and comparative psychologists. Behavioral psychologists questioned the distinction between “innate” and “acquired”, pointing to a series of findings on development that showed that the criteria used to distinguish between the two were not empirically supported, and the influence of genetics on behavior was expressed through developmental processes, far more complex than argued by nativistic theories. We now have extensive evidence showing that species-typical behaviors appear at times different from birth, that experience and learning influence this behavior in indirect ways, that isolation does not warrant exclusion from environmental influences, including the stimulation of the individual itself, and that the so-called instinctive behavior is plastic in response to environmental variation. New developments also provide hypotheses on how learning may become assimilated and develop as “innate” behavior, and how differences in motivation and expression of behavior are often more the result of epigenetic than genetic differences (e.g., Jablonka and Lamb 2005). A better understanding of the role of development in the integration of genetic input and experience has built on the concept of instinct refining its use in current scientific explanation of behavior.

After the debate on instinct, psychologists adopted the concept of “drive” as an internal force activated by deprivation that energizes a motivational system, resulting in the performance of an organized set of behaviors in response to specific environmental stimuli. Many authors considered drive as the force moving an animal to obtain a consummatory stimulus; that is, the motivation for appetitive behavior. The empirical

evidence, mostly based on hunger, thirst, and circadian rhythms, was difficult to interpret and the concept grew confusing because different authors used it as behavior, as a motivational construct, or as a physiological state; however, the three meanings were often not in agreement in a single set of observations. Despite the efforts of theorists like Clark Hull to make effective use of the concept, it was vague, and not easy to integrate with the knowledge of mechanisms for different motivational systems (Bolles 1975, p. 217).

A universal measure of motivation is the approach/withdrawal response thought of as an organizing principle to understand biphasic processes in all phyletic levels, allowing the integration of simple and complex adaptive responses. In addition to approaching or withdrawing, motivated behavior is often expressed through choice. These and other more complex responses are expressed as an organized and hierarchical structure that may be inferred from the observation of behavior in time and space. This has been recognized in ethology and comparative psychology and has given place to a scheme of organized behavior that integrates the role of genetic and environmental information through cognitive mechanisms such as perception, memory, learning, and motivation (Shettleworth 2010, pp. 33–35).

A simple organization of motivated behavior uses two categories: appetitive and consummatory responses. Appetitive behavior increases the probability of a functional outcome and includes the display of some preparatory responses, as well as providing signals to competitors or conspecifics. In contrast, consummatory behaviors terminate a motivational sequence and relate more closely in time and space to the functional role of behavior. For example, in feeding, appetitive responses include an increase in motor responses, general search for feeding areas, prey/food selection, and others. Consummatory responses include capture, food handling, chewing, and food ingestion. The use of this simple model to understand the behavioral organization of the sexual response shows a more complex sequence that includes an additional category of responses

linking appetitive and consummatory responses: precopulatory responses (Pfaus et al. 2001). Appetitive responses include motor activation, searching, and grooming; precopulatory responses include arousal, solicitation, pursuit, and in general courtship responses; and copulatory responses include mounting, copulation, lordosis, squatting and other receptive behaviors, and orgasmic responses such as ejaculation. Appetitive responses are more flexible and more likely to be influenced by learning, whereas consummatory responses tend to be more species-specific and stereotyped (Burghardt and Bowers 2017). The appetitive-consummatory distinction has been useful to organize empirical questions at all levels of Tinbergen's explanatory taxonomy.

### **Sexual Behavior: An Integrated Model for the Study of Motivation**

In this entry, sexual behavior will be used to illustrate the main concepts of motivation. Unlike feeding or drinking, sexual behavior is not regulated. Most of the literature on regulatory systems, such as feeding, is very detailed in explaining behavioral and physiological mechanisms, but mainly centers on the proximate causes of behavior; thus, showing the possibility of integration between proximate and ultimate causes of behavior is a more challenging task. Sexual behavior, a nonregulatory system, allows for this possibility.

All organisms have evolved and behave to maximize reproductive success (Wong 2000, p. 221). Given the variety of ecological conditions in nature, there are multiple solutions to this general principle of evolution. Sexual reproduction is one solution to the reproductive problem; it has been argued that the main advantage of sexual reproduction is its capacity to produce variability in offspring that allows them to respond to variations in environmental conditions.

Males and females of many species show differences in morphology, physiology, and behavior. Darwin developed Sexual Selection Theory to explain the evolution of such dimorphism. According to his theory, certain dimorphic traits result from two processes: competition among

same sex individuals for sexual partners (intrasexual selection) and preference for certain characteristics in the opposite sex (intersexual selection).

The combinations of these processes derive traits that may be incompatible with traits resulting from natural selection. Sexual selection not only results in exaggerated morphological traits but also in behavioral specializations such as acoustic signals, visual displays, and olfactory cues that attract potential reproductive partners (Alcock 2001, pp. 348–351).

Differences in the characteristics of sexual gametes between males and females have been thought to promote sexual differences in reproductive behavior. Limited quantity and immobility of female sexual gametes make them a valuable resource for males, leading to the evolution of differential reproductive strategies. The interaction of male and female strategies results in a variety of mating systems, associated with variations in motivation and behavior (Wong 2000, p. 17).

### **Sexual Differences in Reproductive Behavior**

The differences between male and female sexual behavior have often been described in terms of their relative contributions to the production and rearing of offspring. This approach has emphasized the role of males in courtship and copulatory behavior, and the role of females in nesting and caring for their offspring. Nevertheless, both males and females participate in most aspects of sexual reproduction, and thus, a comparison of their roles, behavior, and motivation should be done on the basis of equivalent categories of behavior. Frank Beach (1976) developed a taxonomy of sexual behavior that can be used to analyze differences between males and females using similar criteria. Sexual behavior is expressed in attractivity, proceptivity, and receptivity which represent the interrelated stages of reproductive interaction between males and females. They have some correspondence with the previously presented taxonomy of appetitive, precopulatory,

and consummatory behavior; despite a tremendous variety in these characteristics among taxonomic groups, this categorization is helpful to understand male-female differences in sexual behavior and their underlying causes.

*Attractivity* is inferred from the behavior of the pair mate and represents the value of an individual as a reproductive partner. *Proceptivity* refers to responses indicating the attraction to a potential sexual partner; some indicators are orientation, approach, solicitation, and contact behavior. Courtship responses are generally considered proceptive behavior and tend to elicit proceptive and receptive responses in the mating pair. *Receptivity* refers to consummatory responses to solicitation and stimulation by the sexual partner.

A behavioral repertoire in all three categories has been described both in males and females across many species, and differences in their expression are observed between both sexes. It has been found that female attractiveness can be determined by characteristics that indicate reproductive condition and their capacity to invest and care for their offspring. Male attractiveness can be determined by characteristics indicating their ability to provide direct resources (i.e., protection or parental care) or indirect ones (i.e., genes) to the female or the offspring (Alcock 2001, pp. 341–353). Hormones may affect the level of attractiveness of an individual by influencing both their appearance and their behavior. Hormonal fluctuations are associated with changes in the coloration of feathers, vocal patterns, and other secondary sexual characteristics (Adkins-Regan 2005, p. 61).

The expression of proceptivity is also different in males and females. For instance, it has been observed that male Japanese quail (*Coturnix japonica*) approach and remain close to a window that provides visual access to a female conspecific, but under equal conditions, the same response was not detected in females (Mills et al. 1997). Nonetheless, when females are visually exposed to a male quail and later removed from an experimental arena, females are more likely to go to the area where the male was previously seen (Gutiérrez and Domjan 2011). A similar effect has been observed in rats (*Rattus norvegicus*), especially when females have been allowed to pace

their approach responses to males (see Pfaus et al. 2001). Frequently, the issue at hand is that selected behavioral measures can sometimes be insensitive to variations in motivation and may be mistakenly interpreted as the absence of motivation, rather than as a methodological artifact. Along these lines, it is necessary to explore multiple behaviors to identify measures of motivation. For example, in addition to approaching an area where a male has been previously observed, other proceptive behaviors (e.g., pacing in front of males) have been identified in birds and rodents (Carter 1992, p. 73). Hormones may also influence levels of proceptivity. For instance, in female mammals, elevated concentrations of estrogen increase their sexual interest in males; females approach males and show precopulatory behaviors toward them (Carter 1992, p. 72).

Receptivity may be expressed in either an active or a passive way and may also be affected by hormonal changes (e.g., Lee and Gorman 2000). Active receptivity has been studied in the lordosis response in rodents and other mammals as well as squatting in birds. Both lordosis and squatting are described as the female lowering her body, raising her back toward the male, and remaining in this position long enough to facilitate the mounting and sperm delivery into the female reproductive tract. Lordosis and similar responses such as squatting are indicators of motivation of the female toward sexual interaction. A measure called the Lordosis Quotient has been developed to measure the magnitude of such responding (Carter 1992, p. 74); related measures might be developed for squatting and other receptive responses. Passive receptivity is interpreted as the female remaining in an area where a male is present. The proper evaluation of this response, however, requires that the female is not constrained by other variables such as essential resources, offspring, or other factors that motivate her to remain in the area, confounding sexual and other sources of motivation.

Other reproductive behaviors such as response to courtship and nest construction are often seen as receptive behaviors. For instance, in ring-necked doves the reproductive sequence starts with the male courtship behaviors directed towards the female. The female responses to

courtship are followed by the selection of a nesting site, building of a nest, and copulatory interaction. After this interaction, the female lays eggs and starts the incubation process (Silver 1992, pp. 417–418). Although the behaviors of males and females previously described are categorized as receptive behaviors resulting from the social stimulation produced by the reproductive partner, it is not always easy to differentiate between proceptive and receptive responses due to the fact that the sequence includes behaviors common to both stages of sexual behavior.

Male sexual responses in many species are more easily observed and measured than female sexual responses, and sexual behavior is often studied in the laboratory in situations in which subjects are deprived of sexual interaction. Under these conditions, males tend to copulate readily after being presented with female partners, whereas females do not show the same type of response or immediate proceptive or receptive behaviors. Furthermore, under laboratory conditions, females are not usually given the opportunity to avoid or escape exposure to a male or to select their mate. Therefore, lack of female responsivity can be misinterpreted as lack of motivation. However, changes in experimental protocols to study sexual behavior have clearly shown that females are motivated to sexually interact with males, but their behavior is often subtle and depends on their possibility to control their access to males. Thus, the understanding of differences between males and females should take into account possible differences in expression rather than the level of motivation (Gutiérrez and Domjan 1997; Pfaus et al. 2001).

## Sexual Competition and Mate Choice

According to Sexual Selection Theory, males tend to be more competitive than females, and females tend to be more sexually selective than males. This seems to be the case in polygynous species, but in relatively monogamous species, these differences tend to decrease, and competition and selection become relatively common in both sexes. Competition and choice complement each other, and result from a balance of interests and

strategies of males and females to increase their fitness. Courtship behavioral patterns play a special role connecting those interests. They attract a mate, provide information to the selecting partner, elicit sexual responses, and synchronize those responses as well as the physiological mechanisms supporting them (Ryan and Jordan 2017).

Sexual competition, courtship, and mate selection result in behaviors that are indicators of sexual motivation; thus, the mechanisms responsible for these responses are ultimately, motivational ones. Whether competition and selection directly result in measurable gains for males and females is not always easy to determine empirically; however, courtship and mate choice lead to sex and its rewarding properties. Sometimes, motivational systems may influence behavior in different directions. The resulting trade-off may increase mating success, but at the same time, it may decrease survival of the individual (Wong 2000, p. 222). In male-male sexual competition, for example, males sometimes incur high risks of predation, injury, or starvation.

Male-male competition may occur before, during, and after copulation. Competition at each of these moments is motivationally controlled by mechanisms at proximate and ultimate levels, as will be explained later in this entry. In some species, males compete for and defend a territory during the mating season. Females then select males on the basis of the quality of those territories. For example, Japanese quail form territories at the beginning of the reproductive season and females select a male to form a pair during the season (Mills et al. 1997). Male-male competition can take other forms as well, including scramble competition, resource defense, harem defense, social hierarchies, and mate guarding, among others (Alcock 2001, pp. 327–340).

Male and female mate selection are often established according to different criteria; females select males on the basis of resource production and physical as well as behavioral traits associated with survival and reproduction capacity, whereas males select females based on their reproductive capacity and health. In species in which both males and females provide parental care, reciprocal mate selection is common (Ryan and Jordan 2017). In any case, the selective partner must

compare among possible mates, based on information provided by physical and behavioral characteristics. In some cases, the information is provided by the results of a contest between competitors. In other cases, however, the information provided is an indirect measure of the quality of the sexual partner. For example, pied flycatchers (*Ficedula hypoleuca*) prefer males with a jet black and white plumage that show better parental care, over males with a less defined plumage color and lower parental qualities. Similarly, male house finches (*Haemorrhous mexicanus*) with a bright red patch in their plumage are more likely to resist parasites and are preferred over males with a duller plumage (Alcock 2001, pp. 345–346). The relative roles of direct and indirect benefits on motivation of mate choice and sexual behavior constitute an unresolved issue and require empirical evaluation.

The genetic and epigenetic mechanisms of sexual selection have not been extensively studied. For some species, mate choice is likely the result of developmental processes. Animal behavior researchers have described the role of early learning in mate selection in a number of species, especially birds. For example, female Japanese quail prefer males with some phenotypical similarity (cousins) but not closely related males (brothers) (Bateson 1982). It is unclear which male physical characteristics determine this decision. In a more recent study, it was found that in a choice situation, female quail preferred males different from those they had previously encountered during rearing (Pérez and Gutiérrez 2006).

Motivation for and choice of mates might also be influenced by social factors. For instance, female quail are more likely to choose males that have been selected by other females, and these males are more likely to fertilize the female's eggs than nonpreferred males (Persaud and Galef 2005).

Sexual selection may influence other reproductive behaviors and physiological responses in the female. For example, females of a number of bird species are likely to make a larger investment on offspring of a more attractive male, before and after hatching. Female zebra finches (*Taeniopygia guttata*) have been found to lay eggs with higher levels of testosterone when those eggs have been

fertilized by a preferred male (Alcock 2001, p. 341). The proximate mechanism for this effect seems to be activated during the yolk phase, and it results in increased growth and begging rates after hatching, giving chicks an edge in their survival and reproduction. This phenomenon has not been extensively explored but shows motivational effects on developmental and evolutionary mechanisms of behavior.

## The Role of Learning in Sexual Motivation

As many other motivational systems, sexual behavior is more likely to be effective if flexible to changes in the environment. Learning provides the basis for that flexibility in several ways. As previously pointed out, appetitive responses (and even consummatory ones) are likely to be influenced by learning. Changes in responsivity to stable sexual stimuli (i.e., habituation and sensitization), capacity to predict a sexual partner (i.e., Pavlovian conditioning), changes in behavior to the environment in order to obtain an outcome (i.e., instrumental learning) and learning from others to select a sexual partner or a sexual response (i.e., social learning) have all been investigated using animal and human models and have important implications on how we understand the role of motivation in sexual behavior.

Sexual learning phenomena have been investigated in a variety of species, including insects and other invertebrates, fish, reptiles, birds, and mammals (see Domjan and Holloway 1998, for a review). Sexual learning has been studied following a Pavlovian conditioning procedure. Hollis et al. (1989) studied the conditioning of sexual behavior in the blue gourami fish (*Trichopodus trichopterus*). They presented each fish of a male-female pair with a light followed by visual access to the other fish. As a consequence, both males and females showed an increase in frontal displays; males increased their courtship appeasement responses and decreased aggressive responses to their pair-mate. This suggests that learning has a functional effect and provides an adaptive value to individuals who are able to

predict the presence or availability of a conspecific.

Pavlovian conditioning makes appetitive and consummatory responses more effective. For example, male rats copulate quicker if they encounter a copulation partner after the presentation of a conditioned stimulus previously paired with exposure to a female (Krause and Domjan 2017). Similarly, male quail presented with a conditioned stimulus preceding the release of a sexually responsive female, copulate faster and more often in a sexual competition situation than a male without the same learning experience (Gutiérrez and Domjan 1996).

The role of learning on other competition situations has also been explored. The effect of dominance on reproductive access has been extensively documented (Alcock 2001, p. 331); the clearest effect is that dominant males of many species, which tend to have more access to females, have more copulations and fertilize more eggs. A general correlation of dominance with steroid production has been found but the relation is not simple and may be modulated by other factors such as social experience and learning (Adkins-Regan 2005, pp. 94–98). Subordinate males often have to use alternative strategies if they are to sire offspring. Montoya et al. (2016) explored the possibility that learning may be one of these alternative strategies; they showed that subordinate male quail improve their copulation efficiency in a competition with other dominant males, after learning to predict the presence of a female conspecific.

Pavlovian conditioning may also increase the production of sperm in terms of volume and number, fertilization in a sperm competition situation, and fertilization rate in noncompetition situations (see Krause and Domjan 2017, for a review). All these findings show that learning may have important effects on appetitive and consummatory responses, including copulation and fertilization. A shorter latency to copulate, assuming the costs of learning, seeking new opportunities for sexual interactions, changing the hierarchical organization of social and sexual responses, and physiological changes in response to challenging situations are all indicators of motivational

change, but further explorations are necessary to determine the interaction of learning and motivation in these situations.

Instrumental learning also affects sexual motivation; male rats trained in a runway increase their running speed to have access to a female rat, and press a lever for access to sexually receptive female rats; a similar effect has been demonstrated for females trained to press a lever to selectively have access to one of two males. In a choice situation, females in estrus prefer a male over a female. This preference decreases during pregnancy and increases again during lactation. An instrumental response of choice has also been observed in pigeons (*Columba livia*), Rhesus monkeys (*Macaca mulatta*), and other species in a number of instrumental paradigms (see Pfau et al. 2001, for a review).

Male Japanese quail increase their running speed in a straight alley when reinforced with copulatory access to a female quail (Baquero et al. 2009). The similarity of the instrumental response to the approach response using a Pavlovian paradigm suggests a similar motivational structure. The magnitude of the Pavlovian response and the choice response is related to the amount of sexual reinforcement and is mediated by testosterone (Domjan and Holloway 1998).

One important effect observed in the study of the sexual system is that learning seems to affect both appetitive and consummatory responses. As pointed out before, in other behavioral systems, the role of learning has been documented mostly on appetitive responses. It is still unknown if this indicates that reproduction may be somehow different from other motivational systems (i.e., regulatory systems).

## Hormones, Sexual Motivation, and Ecology: The Case of Birds

For many animal species, especially those in regions with more extreme climate variability, reproduction occurs at certain times of the year, usually timing the availability of resources. This timing in breeding has been selected over hundreds of thousands of years; that is, animals who

bred and raised their offspring when food resources were scarce or weather conditions were extreme were less likely to have surviving offspring and vice versa. Selection of certain behaviors implies the selection of anatomical structures, physiological mechanisms, and other biological characteristics associated with those behaviors. In this section, I will show how hormonal changes are related to multiple environmental factors associated to the onset and maintenance of sexual motivation, especially in birds.

In species living in mid and high latitudes, the most important environmental factor regulating reproduction is photoperiod. Taking into account the rate of change regarding the day's length is the same every year, it constitutes a reliable cue for many animals living at those latitudes to predict changes in the availability of resources and other conditions necessary for successful reproduction. There are, however, other factors such as temperature, humidity, social signals, and others that are used as additional cues at different stages of reproduction and serve as tuners of these activities (Wingfield et al. 2000).

In species living close to the equator and in deserts, photoperiod is not relevant as a proximate factor associated to reproduction. For instance, zebra finches living in the South Australian desert remain sexually inactive most of the time despite being pair-bonded, but when it rains in that region, reproduction is activated, and they begin nesting and egg laying. In this particular case, humidity is the major factor involved in triggering reproductive behavior (Adkins-Regan 2005, pp. 68–69).

Most research on the effects of light on sexual behavior in birds has been performed on passerines species, some domestic species such as the fowl and the pigeon, and the Japanese quail. Males are usually studied because their physiological and behavioral responses are more easily observed, but as noted elsewhere, a better understanding of parallel processes in females is important and should be of continued interest to researchers.

In mid and high latitudes, reproduction occurs during spring and summer for most species. When the day length reaches a certain level, some

changes associated with reproduction take place. In the wood pigeon, the testicular weight is very low (close to 0) between the months of November and March. During April, however, the testicular weight increases dramatically, then it increases at a steady rate and reaches its peak between July and September, after which it decreases very fast (Gwinner 2012). These changes in testicular weight are symmetrical to the photoperiod. When the day photoperiod is at about 12–13 h of light and 11–12 h of darkness, the wood pigeon starts its increase in testicular size.

The symmetry between the pattern of testicular size and day length does not apply to all species. Some birds show a pattern of rapid increase, a relatively short peak period, and then a rapid decrease even though there is still enough photostimulation to support their reproductive state. This phenomenon is called *refractoriness*, and it has been observed in the rook (*Corvus frugilegus*), the mallard (*Anas platyrhynchos*), and some sparrows. Good examples of this effect are observed in the house sparrow (*Passer domesticus*) and the white-crowned sparrow (*Zonotrichia leucophrys*).

During the breeding season, male white-crowned sparrows arrive early to the breeding area and establish territories that later will be visited by the females. The hormonal and sexual activities of males and females are not synchronized at that time. Males arrive to the breeding area when their testes are almost fully grown. This corresponds to high levels of testosterone and LH. Light stimulates follicular development in females, but when the females arrive, the follicle is still not completely mature and only fully develops as a result of interactions with the males in the breeding area (Wingfield et al. 2000). High plasma levels of testosterone in that moment may contribute to keep relatively high aggression levels in the males in order to defend the territory formed by the pair. High levels of male-male aggression are observed during that time. When the female reaches reproductive condition and sexual receptivity, males mate-guard the females to prevent extra-pair copulations, common to many species of birds (Adkins-Regan 2005, pp. 102–108). After the first brood,

the sparrow shows spontaneous testes regression even though there is still enough photostimulation to maintain this bird in reproductive condition, followed in some occasions by a second breeding period.

The phenomenon of refractoriness contributes to the repetition of reproductive stages across the mating season and a response to unpredictable variation in environmental conditions, migration, and other life-cycle changes (Ramenofsky 2011). Some species such as the Californian quail (*Callipepla californica*), the bobwhite quail (*Colinus virginianus*), and the Japanese quail do not show a pattern of gonadal growth characteristic of refractory species. In fact, in a laboratory setting it is possible to keep Japanese quail in fully reproductive conditions by maintaining a stable photoperiod of 16 h of light and 8 h of darkness (Mills et al. 1997).

Temperature changes may have direct and indirect effects on different aspects of reproductive motivation and behavior in many species. In some cases, the effect of temperature on sexual behavior has been argued to be direct. In the domestic fowl, extremely low and extremely high temperature affects fertility in both males and females (Huston 1975). In the *pugetensis* variety of the white crowned sparrow, an increase in temperature promotes gonadal growth in females, whereas in the *gambelii* variety it does not. This is likely related to ecological conditions of the two populations. *Z. l. pugetensis* is a migrant species and the onset of the breeding season shows a variation; thus, it is more susceptible to other environmental cues such as temperature (Wingfield et al. 2000). In Japanese quail, for which light is the most important trigger of sexual behavior, it has been observed that an important increase in temperature, even during short-day photoperiods, may stimulate gonadal growth and subsequently, sexual behavior (Mills et al. 1997).

Indirect effect of temperature on the reproductive conditions of birds is observed in the nesting of the great tit (*Parus major*). Changes in temperature affect leafing of birch and the availability of caterpillars, the main supplies of food for the great tit. This supply allows females to store enough fat

necessary for egg formation. Changes or stability in the food supply may also affect fattening, molting, and migration in white crowned sparrows (Ramenofsky 2011).

The preceding studies suggest that food availability and quality might be important cues in the development of certain reproductive behavior in some species. Certain elements in the diet of birds might be essential for specific aspects of reproduction, such as oviposition. Various researchers have shown that food quality may affect gonadal development in several species (Lee and Gorman 2000). For example, during the fall, a time in which photoperiod is unable to maintain gonadal growth, Payne (1969) fed tricolored blackbirds (*Agelaius tricolor*) with insects, a diet rich in protein. As a result of this particular diet, the subjects grew their testes to levels that were significantly higher than the ones maintained before the diet manipulation. Similarly, pinyon jays (*Gymnorhinus cyanocephalus*) fed with cones of the pinyon pine show gonadal growth; for this species, the availability of food is a reliable signal for sexual and reproductive motivation and action, allowing the individuals to cope with variations in food supply in a changing environment (Visser et al. 2004).

Besides temperature and food availability, other environmental cues are believed to be responsible for motivation and the activation of sexual behavior. As previously mentioned, in Australia, the zebra finch shows gonadal growth with increases in atmosphere humidity, and also in laboratory conditions with the introduction of fresh water after deprivation. In tropical species, the main factor determining the onset of sexual activity seems to be the changes in humidity. Some tropical species are photosensitive and may show endocrinological changes to slight photoperiod variations. The final trigger for courtship, copulation, and nest-building, however, seems to be rainfall changes; studies in tropical Africa (see Adkins-Regan 2005, p. 70) showed that in male blue-eared glossy starlings (*Lamprolornis chalybaeus*) changes in rainfall from the dry season to the wet season were associated with increases in plasma LH and testosterone, and territoriality. Since rainfall in many regions of the

tropics does not occur on a strict schedule every year, it is believed that it is not the rain itself that produces the hormonal changes, but that the change from the dry season (which is inhibitory) to the wet season is what elicits those changes. When the rainy season is not strong enough, such a disinhibitory effect does not take place. It is important to note that hormonal changes from the dry to the wet season are not universal in males of tropical species; for example, male stonechats (*Saxicola rubicola*) do not show significant LH and testosterone changes from the dry to the wet season. Rainfall might also control reproductive behavior in other ways. In the jungle fowl (*Gallus gallus*), which inhabits some regions of southeast Asia, sexual behavior occurs during the dry season. Since this species nests on the ground, the inhibitory activity of rainfall has a clear adaptive effect (Nishida et al. 2000).

Signals that are not related to environmental changes, but indicate the presence of conspecifics, may have an effect on the hormonal state, motivation, and sexual behavior of birds and other species. General sexual experience may affect hormonal levels of some birds at the beginning of the next mating season. For example, visual exposure to a female but not a male induces an increase in testosterone level in ring doves (*Streptopelia capicola*) (Silver 1992). In general, the presence of a sexual partner induces gonadal growth in males and ovarian development in females of many vertebrate species. This effect may result from the presentation of acoustic and other social signals (Wingfield et al. 2000).

Sexual experience may affect the level of the sexual response of male Japanese quail to females, as well as signals associated with them (Cornil and Ball 2010). This effect is evaluated by measuring responses such as the approach to those signals or to females, and copulation with females. It has been found that Japanese quail are able to learn complex relations between neutral signals and access to a sexual partner (Domjan and Holloway 1998). Changes in hormone production are flexible and occur in response to changes in the environment. For example, male mice (*Mus musculus*) exposed to females increase the production of LH and testosterone. This

response can be learned; using a classical conditioning procedure in rats, a conditioned stimulus (previously neutral) induced the production of LH and testosterone, before the presentation of the unconditioned stimulus (a female rat) (Adkins-Regan 2005, p. 22).

Although hormonal changes produced by learning have not been extensively studied, the effects of hormonal changes over learning and performance are better known. For example, in Japanese quail, a decrease in sexual motivation produced by functional castration disrupts the performance and learning of the approach response to an arbitrary stimulus associated to a sexual partner (Domjan and Holloway 1998).

In some cases, the behavior of the mate may elicit the onset of certain aspects of reproductive behavior. When female ring doves are exposed to courtship behavior by males in reproductive conditions, they ovulate, while the exposure to castrated animals does not have a similar effect. In this case, the courtship behavior seems to act as a cue of the reproductive condition of females. Similarly, latency of egg-laying might be reduced by exposure to the male's courtship sounds and display in barbary doves (Silver 1992).

Male white-crowned sparrows maintain high levels of LH and consequently of testosterone in the presence of females that are laying eggs. Additionally, males of this species keep high levels of LH and testosterone if their female mates are treated with estradiol and maintained sexually active and receptive (Wingfield et al. 2000).

Interactions with conspecifics of the same sex may also increase other behaviors associated with sexual activity in some species. For instance, white-crowned sparrows show increased levels of testosterone when exposed to other males whether the stimulus males are sexually active or not. In those cases, aggressive behavior increases for some time and then decreases to baseline levels (Wingfield et al. 2000). This suggests that the introduction of new males in the territory of males represents a motivational change, particularly an increase in sexual competition that could explain the increase in testosterone levels. This has been called "The Challenge Hypothesis."

This idea was tested in song sparrows (*Melospiza melodia*) by introducing a caged male in the territories of other males and by playing territorial songs; this procedure induced attacks by the residents on the intruder. When captured (later on), males of those challenged territories showed higher levels of testosterone than males of other nonchallenged territories. Competition with other males might explain why higher levels of LH and testosterone have been found in free-living animals than in laboratory subjects. This effect is dynamic, as the removal of the social challenge is followed by a decrease of testosterone levels and aggression (Wingfield et al. 2000).

A relation between testosterone levels, sexual motivation, and mating systems has been found. Species with a polygynous mating system maintain, in general, higher levels of testosterone, while species with a monogamous mating system keep lower levels of testosterone, but induced changes in androgen levels might induce a change in mating system. This relationship between mating systems and hormone expression is not simple, but is modulated by parental care; males of species that provide parental care show lower levels of testosterone when caring for eggs or young, but this androgen level and related aggressive behavior increases if exposed to competing males (Wingfield et al. 2000).

The previous findings would suggest that in polyandrous species, females would have higher levels of testosterone than males, since in many of those species females keep large territories with several males in them. Studies on the hormonal levels of polyandrous females, however, do not support this idea. Goyman and Wingfield (2004) have found that female black coucals (*Centropus grillii*), a polyandrous species, mate with more than one male. They are larger than males, are more vocal, defend territories, and have a higher reproductive rate than males. However, they do not present higher levels of gonadal steroids than males. The pattern of prolactin production for sex-role reversed species differs from the androgen production. In these species, the level of prolactin (a hormone that regulates incubation in birds) is higher in males than in females (Eens and Pinxten

2000). The implications of these pattern differences for behavior and reproductive motivation remains to be fully understood.

## Conclusions

The study of motivation has been central to psychology for the last century. The main theories of behavior have attempted to explain what moves individuals to action. Those explanations have centered on variables, internal and external to the organism, on levels that can be organized in time (from synchronous to evolutionary), and structure complexity (from molecular to social).

Comparative psychology provides a strategy to evaluate motivation at different levels of explanation as the ones proposed by Tinbergen. It provides a systematic approach to identify mechanisms of motivation at behavioral and physiological levels; it offers a strong body of knowledge to understand the relationship between development and behavior, and it provides a systematic approach to study the origin and functionality of behavior across species.

An integrative approach is demanding because it requires the extension of mechanistic understanding, to ecological and evolutionary views. Usually this starts by following a heuristic exploration of how mechanism relates to adaptation, but it must move to empirical evaluation of such speculation. The study of learning has recently achieved that step. After decades of speculation on the adaptive value of conditioning, recent empirical evaluation has shown that learning affects proceptive and receptive responses in several species of vertebrates, improving fitness both in males and females. This is possible through changes in motivation, memory, perception, and other behavioral and physiological processes. Similarly, the study of the relations between hormones, ecological conditions, and behavior, all isolated fields of study in the past, are becoming integrated to show a fascinating picture relating behavioral and physiological mechanisms, environmental constraints, and evolutionary history. Endocrine processes are critical mediators of motivated behavior. They not only contribute to

organize anatomy, physiology, and behavior but also activate the proper behavioral sequence under specific environmental conditions. Clearly, they are not the only motivational force in sexual behavior, but a solid understanding of their mechanisms can be a great basis for an integrative view of reproductive behavior.

## Motivational State

Daniel E. Alarcón

Department of Psychology, University of Chile, Santiago, Chile

## Introduction

Motivational states are physiological internal states in the organism that play an important role in initiating behavior, selecting actions to perform, and orienting the actions to achieve desired goals. Motivational states are critical because they help the organism prioritize behaviors oriented to obtain access to resources that are required to maintain a balanced well-being and, in extreme situations, for survival. Some of the better known motivational states include the states of hunger and thirst, and they can activate specific behaviors oriented to obtain food and drink.

In the laboratory, a motivational state can be inferred by assessing the effect it has on the performance of certain actions. For instance, we can restrict access to food for some animals (food deprivation) and compare how this manipulation affects the performance of pressing a lever that delivers food, relative to animals that were not food-deprived. We can also study the motivational state at a physiological level, for instance, by determining the brain structures and circuits involved in its activation and termination as well as the groups of neurons and neurotransmitters that play a role in these processes.

Motivational states can be regulated by not only homeostatic mechanisms that aim to maintain a biological balance in the organism, for instance, blood glucose levels, but also by non-homeostatic mechanisms, for instance, social events or emotional states. Learning processes are also deeply involved in the development and activation of motivational states, contributing to the acquisition and performance of behaviors oriented to terminating them. Here is a brief review of some of the motivational states of hunger and

## Motivation Condition

### ► Drive State

thirst, the mechanisms responsible for them, and their relationship with learning processes.

## Hunger

Early accounts of the motivational state of hunger gave particular attention to stomach contractions as an indicator of hunger and the initiation of eating behaviors (e.g., Cannon and Washburn 1912); however, this idea was discarded. Instead, evidence supports the existence of homeostatic mechanisms that keep track of the levels of blood sugar and fat, which stimulate the initiation or cessation of eating in order to maintain an optimal state in the organism. In the digestive system, including the stomach, duodenum, liver, and pancreas, there are receptors that detect fluctuations in the level of glucose. When glucose levels decrease, these organs send signals to the central nervous system (CNS) to initiate eating behaviors, and when the glucose levels increase, signals are sent to stop eating (Cumming et al. 2004; Thorens 2011).

In the CNS, the hypothalamus has been shown to play an important role in eating. According to the influential “dual center model,” there would be a specific center for feeding and another separated for satiety, the former located in the ventrolateral hypothalamus (VLH) and the latter in the ventromedial hypothalamus (VMH). The dual center model was based on early studies showing that lesions in the VMH resulted in animals eating excessively, whereas lesions in the VLH resulted in animals that did not eat. Contemporary studies show that the role of the hypothalamus in feeding and satiety is more complex, involving areas such as the arcuate (ARC) nucleus in the hypothalamus, as well as projections to other brain regions, for instance, those in the reward pathway, e.g., ventral tegmental area (VTA) (Farr et al. 2016; Saper et al. 2002; Timper and Brüning 2017).

The motivation to eat might also be regulated by long-term processes. According to the set point theory, each individual has a body weight determined by its genes, and feeding and satiety depend on this set point. The organism could regulate and determine the state of the organism

by receptors of specific hormones such as leptin and insulin. When we lose weight, our levels of leptin and insulin decrease, whereas the opposite can be observed when we gain weight (Farias et al. 2011; Weinsier et al. 2000).

Although these homeostatic processes can explain part of the motivational state of hunger and eating behaviors, humans also eat in circumstances in which homeostasis is not disrupted, for instance, in social circumstances or in response to learned stimuli associated with food. The effects of learning on the motivational states and behavior are described below.

## Thirst

The motivational state of thirst can be activated by at least two different types of homeostatic mechanisms: volumetric and osmometric thirsts. Volumetric thirst is caused by mechanisms related to the fluids located outside the cells of the body (extracellular) and osmometric thirst by a mechanism related to water levels inside the cells (intracellular).

Volumetric thirst occurs when the volume of extracellular (but not intracellular) fluids decreases, for instance, because of blood loss, diarrhea, or vomiting, in the state known as hypovolemia (Stricker et al. 1992). This reduction of the blood volume is detected by the kidneys, which start producing and secreting the enzyme renin into the system. This enzyme interacts with the liver resulting in the release of vasoconstrictor angiotensin II, which increases blood pressure by narrowing the blood vessels. Angiotensin II also stimulates the adrenal glands to produce aldosterone, causing the organism to reabsorb sodium and water resulting in an increment of blood volume and blood pressure (Stanhewicz and Larry Kenney 2015).

Osmometric thirst occurs when the solute concentration in the extracellular fluid increases, causing the body cells to lose water via osmosis. This can happen because of the increased ingestion of salty foods and loss of body fluids via evaporation (as in respiration and sweating), urination, and defecation. Changes in the solute

concentration are detected by cells known as osmoreceptors, which can detect changes in their own volume caused by the loss of water, and send signals to activate drink consumption. The osmoreceptors are located in a brain region that surrounds the third ventricle known as the organum vasculosum of the lamina terminalis (OVLT). Because the OVLT does not have a blood-brain barrier, its neurons can detect changes in the solute concentration of extracellular fluid. When this happens, it activates the median preoptic area, resulting in the sensation of thirst and the activation of drinking behaviors (Stricker and Sved 2000).

Although these homeostatic mechanisms can induce thirst and initiate drinking behaviors, animals do not require being thirsty in order to drink. Just like for hunger and eating behaviors, there are other non-homeostatic mechanisms involved in drinking behaviors.

## Learning and Motivational States

At the beginning of the twentieth century, Pavlov demonstrated that behaviors in anticipation of food delivery, such as salivation, can be learned. He noticed that the external events that preceded the delivery of food began to produce behaviors similar to those naturally produced by food itself but before the animals had access to the food (Pavlov 1927). This first demonstration that physiological events can be learned started a field that has significantly advanced in the last century. Since most of research has been conducted using food deprivation techniques, we will provide examples for the motivational state of hunger, although similar processes are found to be involved in other motivational systems, such as thirst.

As described above, hunger is characterized by many physiological factors, such as a drop in the concentration of glucose in the blood and an increase in body temperature shortly before eating (de Vries et al. 1993; Thorens 2011). Although it has been proposed that these physiological changes initiate food-seeking and food consumption in an environment in which food is readily available or

periodically provided, it is more likely that external cues, such as the time of the day or the amount of light, initiate the internal processes to prepare the organism to eat and digest food (Woods and Seeley 2002). Cues that are consistently present before or during eating become capable of eliciting physiological changes in the organism by increasing levels of insulin (Woods et al. 1977) and dopamine (Mark et al. 1994), which serve to anticipate food and trigger anticipatory behaviors such as salivation. These external cues also become capable of initiating food-seeking responses, and they invigorate eating behaviors even in sated animals (Petrovich et al. 2007).

The interoceptive cues that characterize a motivational state provide information about the delivery of a relevant consequence, and they can also become discriminative stimuli that inform the animal that, by performing a certain range of actions, access to a reward will be granted. Interestingly, internal cues from a particular motivational state, such as cues that signal hunger, can also be used by the animal to anticipate events from a different motivational system, for example, the occurrence of aversive events. For instance, animals can use the information provided by different levels of food deprivation to anticipate the delivery or non-delivery of a foot shock, as indicated by a conditioned freezing response (Benoit et al. 2010).

Importantly, the interaction between motivational states and learning is bidirectional. For instance, a particular motivational state, such as hunger, can be triggered by learned cues, but what an animal learns at any given time is also modulated by the current motivational state of the animal. There is evidence that the value that an animal assigns to a reward will depend on the current motivational state of the animal (e.g., a food pellet will have a larger value if consumed while hungry than sated; Bolles 1972) and that the prediction error, that is, the difference between what the animal expects and what actually occurs, is modulated by the motivational state of the subjects (Laurent et al. 2018).

A motivational state can also shape the content of what is learned, facilitating new learning about motivationally relevant stimuli. Examples of this can be found in conditioned preference

experiments, in which a stimulus, such as a flavor or an odor, is paired with a nutritional reward like sucrose. Learning is evaluated by measuring animals' preference in a test in which they have a choice between two solutions: one with the trained cue and another with a control cue. Animals will consistently prefer the solution containing the cue that was earlier paired with the nutritional reward. This paradigm has shown that at least two types of associations can be established: one between the flavor/odor and the calories of the reward and another between the flavor/odor and the taste. The expression of the animal's preference will depend on one of these associations, which in turn will depend on the motivational state of the animal. For instance, animals will prefer a flavored solution that has been paired with sucrose, but the preference will be larger in animals that were trained in a food deprivation state relative to those trained with free access to food. Interestingly, this difference is maintained regardless if the animals are tested hungry or sated. In contrast, when animals are trained with saccharin, which has no nutritional value, rather than sucrose, the animals' preference for the solution paired with saccharin is not affected by the motivational state of training (Capaldi et al. 1994).

This type of experiment has also shown differential effects of extinction on animals' preference. In extinction, a stimulus that has been paired with a relevant consequence (a conditioned stimulus) is then consistently presented in the absence of the reward, resulting in a loss of its learned properties (Delamater 2004). There is evidence that the animals' preference for a flavored-solution that has been paired with a reward, either with a nutritional value or not, persists after multiple tests, in which the animals are exposed to the flavored solution without the valuable component (Capaldi et al. 1983). However, this preference for a flavored solution paired with a nutritional reward decreases if the animals are either trained or tested in a food-deprived state (Harris et al. 2004).

Another example of the effect of the motivational state on the content of learning can be found in cue competition phenomena, which have been critical for development of the most influential learning models. One of them is latent inhibition,

in which learning about the predictive relationship between a cue and a reward is slowed down if animals have prior experience with the same cue in the absence of any reward (Lubow 1973). Latent inhibition also depends on the motivational state of the animals: if the cue is preexposed to the animals while they are hungry, then learning about this cue as a predictor of rewards relevant to the motivational state of hunger, such as foods, will be retarded. However, learning about this cue and the delivery of a non-nutritional reward, such as saline, will not be affected. In contrast, if pre-exposure is conducted to thirsty animals, then this will slow down learning about this cue and saline, but not between this cue and food (Killcross and Balleine 1996).

## Behavior and Motivational States

Perhaps the more direct link between a motivational state and behavior can be observed on goal-directed actions. As the name implies, a goal-directed behavior is an action oriented to obtain a goal, and its expression depends not only on previous learning about the relationship between the behavior itself and the access to the goal but also on the desirability of that goal (Dickinson and Balleine 1994). A rat will press a lever to obtain food if the animal has learned a relationship between the action of pressing the lever and the delivery of food, but it is also important that the animal is hungry. One commonly used technique to assess if a behavior is goal-directed is to reduce the value of the "goal," which can be achieved by pairing the goal with an aversive consequence. For instance, Adams and Dickinson (1981) trained hungry rats to press a lever to obtain one type of food, and separately, the same animals were exposed to a different type of food. After training, half of the animals received pairings of the food that served as a reinforcer and lithium chloride, which produces illness, while the other half received pairings of the food that was merely exposed with the aversive consequence. In the test, the first group of animals showed a lower rate of responding than the latter, demonstrating that the

desirability of the outcome is necessary for goal-directed behavior.

However, the role of the motivational state on goal-directed behavior is slightly more complicated. As described above, the current motivational state of an animal has a direct impact on the value of an outcome; for instance, food is more valuable when hungry than when not. Thus, motivational shifts from hunger to satiety, for example, should result in a reduction of the outcome value, while shifting from satiety to hunger should result in an increment in the outcome value. However, for this to happen, animals need to have prior experience with the outcome in the corresponding motivational state. For instance, Balleine (1992) trained rats to press a lever to obtain a nutritious reinforcer (different from the maintenance food), and after this, he measured the rate of lever-pressing in a test in which the reinforcer was not delivered. Importantly, before training, all the animals were food-deprived for a period in which half of them had the chance to consume the reinforcer, while the other half did not. Then, all the rats regained access to the maintenance food in their home cages throughout training. Before the test, half of each group of animals were food-deprived again, while the other half were not, and in the test, the hungry rats that had experienced the reinforcer while hungry were the ones that showed a higher rate of lever-pressing relative to the other three groups. The performance of the group that was also food-deprived but that did not experience the reinforcer while hungry did not differ from those groups that were not hungry at test. Balleine (1992) also conducted similar experiments by training animals in a hungry state and then tested them either hungry or sated, finding no differences between these two conditions. However, animals that received exposure to the reinforcer prior to training while sated showed a reduction in the rate of responding relative to the other groups. This phenomenon is known as “incentive learning,” and it refers to the fact that the value assigned to an outcome depends on the animal experiencing this outcome in the relevant motivational state (Dickinson and Balleine 1994).

In contrast, motivational state does not play the same role in habitual behaviors, such as behaviors

that do not depend on the desirability or value of the goal and may develop through extensive training (Dickinson 1985). Habits can be performed when the animals are in an opposite state to the motivational state that corresponds to them; for instance, an animal may perform food-seeking behaviors in a state of satiety and even if the “goal” is harmful to the animal. Several studies have demonstrated that animals will continue pressing a lever that was trained with a food reward even if the food has been paired with an aversive consequence, once the lever pressing behavior has become habitual (Adams and Dickinson 1981).

There is another situation in which behavior does not seem to be affected by the current motivational state of the animal. In some cases, a learned stimulus, such as a light that signals food delivery, can invigorate certain actions, such as pressing a lever to obtain food. In other cases, these stimuli can affect decision-making processes, biasing action selection. For instance, the sound that signals the delivery of a solution can result in animals pressing a lever that gives access to this solution more than a lever that gives access to food (Alarcón and Delamater 2019). This selective effect on behavior persists even after the motivational state of the animal has been shifted or when the value of the goal has been reduced by pairing with an aversive consequence, demonstrating that the control over behavior by learned cues is in some degree independent on the motivational state of the animal (Cartoni et al. 2016).

## Summary

Motivational states are important in the initiation, maintenance, and termination of behaviors that aim to obtain resources necessary to maintain an organism’s physiological balance and survival. Motivational states can be studied from different levels of analysis, for instance, from a behavioral or a physiological perspective. The mechanisms involved in these states are in part homeostatic, such as regulation of glucose in the blood for the state of hunger, but there are also non-homeostatic mechanisms that keep the organism balanced in the long term. Motivational states are influenced

by learning processes, and they can also affect the acquisition of new learning as well as the performance of goal-directed behaviors. However, motivational states do not seem to play the same role in the performance of habitual behaviors or in the invigorating and biasing effect that some learned cues have on behavior.

## Definition

A convergent pattern of morphological and/or behavioral traits in organisms that signal aposematism for predators.

## Introduction

Predators exert strong selective pressures on prey, therefore shaping their defensive strategies. According to the theory of optimal foraging,

**Müllerian Mimicry, Fig. 1** The mimicry ring assembly is modulated by predator decision over time. The prey-predation interrelationship is an important interaction for shaping mimicry ring formation. Some information about the butterfly prey such as palatability level and coloration pattern (on the top) help the operator decide to try (green) or avoid (red) the prey, which changes the community frequency. The capacity to associate the palatability of prey to a black-yellow pattern is beneficial for the operator and the emitters. Furthermore, prey frequency and capacity to know about the unpalatable prey (either learned or innate) are important aspects. The naive predator that does not know about the unpalatability of prey tries all prey in the community, including the unpalatable (Step 1).

After an unpleasant experience, the operator can recognize the unpalatable prey and avoid the aposematic prey (Step 2). Other unpalatable prey are protected by the same coloration pattern (honest signal) and form a **Müllerian mimicry** (Step 3). Some variable and eventual unpalatable prey forms a **Quasi-Batesian mimicry** (Step 4). Finally, when the palatable prey mimics the unpalatable model, a false signal, this forms a **Batesian mimicry** (Step 5). The warning signal increases in efficiency when the frequency of the signal increases; however, the palatable prey that resemble the warning signal decreases the efficiency of the warning signal, and this false signal allows predators to disassociate the palatability from the warning signal (morphological and behavior convergence)

predators tend to maximize their energy absorption per unit of time. During the first step of the assessment phase of a potential prey, the predator needs to distinguish palatable and easy prey from

unpalatable, dangerous or difficult to capture prey (Fig. 1). A naive predator trying the unpalatable prey (Step 1, Fig. 1). The decision to attack or not depends on the animal's cognition through

instinctual behavior (innate) and/or previous experiences (learning). These decisions must be made quickly and accurately, as mistakes can result in high costs including unpleasant experiences, injuries or even death. On the next attempt, the experienced predator starts to avoid conspicuous aposematic prey (Step 2, Fig. 1). To maximize time and minimize costs involved in the manipulation, subjugation and digestion of prey, predators use indirect sensorial cues as colors, smells and sounds. The choices based on these cues select for generalized convergent patterns between prey through natural selection. This scenario explains the origin of conspicuous warning signs (aposematism) and displays of intimidation (e.g., false eyes) (Ruxton et al. 2004; Janzen et al. 2010) (see Steps 3–5, Fig. 1). In this sense, mimicry can be classified as a “meme” (sensu Dawkins 1976), a piece of symbolic information that exists only from the perspective of the operator’s cognition. This interaction has evolved under different selective pressures and sometimes in conflicting ways with other animal demands, such as sexual selection, environmental changes, host plant distribution, phenotypic plasticity and dispersal (Rossato et al. 2018a). These are the adaptive bases for understanding the evolution and maintenance of the different types of mimicry in biological systems (see Fig. 1).

While many different types of mimicry have already been proposed, Müllerian mimicry is a special case. It was first proposed by the naturalist Johannes Friedrich (‘Fritz’) Müller (1821–1897) after he immigrated to Brazil. He formulated an explanation for the similarity between unpalatable species that is now so widely accepted that it is often considered synonymous with the phenomenon itself. In 1879, Fritz Müller proposed the first formal model of mimicry, which was the first mathematical demonstration of the fitness consequences of ecological traits where two unpalatable prey could benefit from mutual resemblance (Müller 1879; Mallet 2001).

In Müllerian mimicry the prey are called co-mimics, which are two or more aposematic organisms that share a similar appearance and together reduce antagonistic interactions by sharing the mortality costs of educating naive or

forgetful predators (see Step 3, Fig. 1). Therefore, Müllerian mimicry includes at least three agents: two or more emitters of the true warning signal and one operator, respectively representing the co-mimetic prey and the predator (Joron 2009). The co-mimic’s signal information could be visual, chemical, tactile, acoustic, electric, or kinetic, depending on the sensorial universe in which the operators and emitters are found. The strong similarity between unpalatable prey results in the reinforcement of the warning signals, which decreases the predation risk and consequently increases the survival rate of the co-mimics (Franks and Noble 2002; Endler 1988). Consequently, individuals with the same signal have a reduced mortality rate, forming a mimicry ring in the same geographical areas or resource-based microhabitats through natural selection (Willmott and Mallet 2004).

Batesian mimicry is another important type of interspecific interaction and is generalized as a tripartite system, in which a sensitive signal-receiver (operator) misidentifies the mimic (false signal emitter) as the model (honest signal emitter) (Vane-Wright 1976). There may be intermediate cases between Batesian and Müllerian mimicry. Quasi-Batesian mimicry (Speed 1993) (Step 4, Fig. 1) is seen when co-mimics, like Müllerian, have different levels of unpalatability, like Batesian. In this case, some prey (emitters) in a mimicry ring are eventually unpalatable or have populations that contain some palatable individuals (see Step 4, Fig. 1). For example, some mimetic ithomiines species acquire defensive pyrrolizidine alkaloids (PAs) only as adults by feeding on certain flowers (Brown 1984). Therefore many ithomiines have little or no PAs and this increases the costs of interaction for unpalatable prey, as in Batesian mimicry. As mimetic rings in tropical sites can be composed of rich assemblages of species, it is more realistic to analyze them as a spectrum of variation in costs and benefits (Step 5, Fig. 1).

Mimicry rings have evolved under different selective pressures between interacting species. Some aspects of animal cognition and behavior evolved into mimicry in distinct scenarios, such as the predator-prey relationship and the coevolution

between co-mimics (Cuthill and Charleston 2012) and between co-mimics and host plants (Ehrlich and Raven 1964).

Considering the ecological aspects of interaction between co-mimics, Müllerian mimicry is comprehended as a kind of mutualistic relationship between aposematic emitters. Moreover, predators and prey are benefited in this interaction, and therefore survival increases for the predator that better associates the aposematic signal to unpalatable prey information, and the convergence of prey on the aposematic signal, thus avoiding the risk of attacks. On the other hand, rare individuals with new variants in the prey population are not recognized as unpalatable by the predator, thus suffering a greater risk of predation (Joron 2009). Therefore Müllerian mimicry evolution is based on the tendency toward a uniformity of aposematic signaling, which signifies coevolutionary convergence. The prey signal is honest in Müllerian mimicry, which means both co-mimics belonging to the same mimicry ring are unpalatable (see Step 3, Fig. 1). On the other hand, the signal is dishonest when one palatable species mimics an unpalatable species, as seen in Batesian mimicry (see Step 5, Fig. 1). In this case, the palatable mimic is benefited by the unpalatable model species.

Another important force to modulate mimicry selection is predation. In predator-prey systems, the dynamics are modulated by the mimicry signal emission of the prey and by the recognition of this sign by the predator. In addition to predator density, the survival of the predator from this interaction consequently regulates prey density, which could decrease a species' dominance through competition and could strongly affect the species composition in one place. This process is called apparent competition (Holt 1977) where predation prevents the monopolization by the most competitive species in the habitat. Just as predators evolved a more efficient predation through the development of certain behavior and structures, prey also evolved to avoid predation threats through mechanisms such as mimetic rings. The defensive strategies adopted by prey when they cannot hide or escape include the production of strong odors due to a chemical secretion or by

pain in addition to chemical substances that make them unpalatable. The association between toxicity and interspecific aposematic displays found in co-mimics reduces the mortality costs of predators and enhances accurate discrimination between edible and unprofitable prey.

Beyond this, the convergent evolution from mimicry could evolve into conflict with other forces during its evolution (Rossato et al. 2018a), including, for example, intraspecific coevolution by female choice and secondary sexual traits. The phenotypic similarities between species from the same mimetic ring could impose disadvantages stemming from mimicry due to possible mistakes in identifying a mate during courtship (Rossato et al. 2018b). Therefore, the mimetic appearance evolves under a trade-off between natural selection of mimetic traits and sexual selection in mimetic species. Wing color is indeed used as an important visual cue in both sexes of butterflies, as is observed in the aposematic *Heliconius erato*'s courtship (Crane 1955).

Visual characteristics associated with chemical defenses are widely used to avoid predation. Whereas camouflaged individuals tend to have patterns that make them imperceptible in their environment, individuals in the mimicry system show a conspicuous aposematic signals. Therefore, mimicry in the environment presents a warning signal to the predator due to its association with unpalatability (Joron 2009).

## Examples of Müllerian Mimicry

According to an informal survey of the scientific journal literature since 1960, mimicry is predominantly a lepidopteran phenomenon (Sherratt 2008). However, this phenomenon has already been reported for other fascinating animal groups such as bumblebees, frogs, coral snakes, bees, birds, ants and fishes, in addition to being suggested for some plants.

The first and most famous case of Müllerian mimicry occurs in the Neotropical butterflies *Heliconius* (see Benson 1972). This is an evolutionary model in biology due to the large intra- and interspecific variation in color pattern and

especially for presenting various mimetic associations, at both specific and sub-specific levels. Four different mimicry rings are typically recognized as “tiger”, “red”, “blue” and “orange” (Mallet and Gilbert 1995). The members of each mimicry ring co-occurring in a similar habitat overlap in the spatial-temporal distribution of distinct mimicry rings, with the most famous case between *H. erato* and *H. melpomene* (Brown et al. 1974). Their spatial distribution in South America shows the occurrence of selective pressures working to generate similar forms, which could not possibly be explained as a coincidence. For example, in these systems birds are recognized as the main agent for mimicry selection, including the maintenance of spatial polymorphisms of the wing color in butterflies. Birds learning to associate the wing color and patterns of co-mimics with unpalatability require a sacrifice from both co-mimics. Therefore, co-mimics must share the burden of the learning predator. Many distinct ways in which the predator learns about the unpalatable butterflies have previously been described for these groups, such as the level of unpalatability (Ihalainen 2006) and co-mimic frequency (Rowland et al. 2010). In addition, the warning signals inherent in wings could be described in terms of coloration (Svádová et al. 2009), pattern (Ihalainen et al. 2008), size (Marples 1993), asymmetry (Forsman and Merilaita 1999), wing shape (Rossato et al. 2018b) and the wing movement pattern used for flight (Srygley and Ellington 1999).

## Conclusion

Müllerian mimicry systems are interesting models for exploring the interface between behavioral ecology and evolution. These complex systems have evolved under different interactions, which modulate the main aspects of similarity between the co-mimics, from coevolution with host plants, with the co-mimics and interactions predator-prey. Additionally, a conflicting force like sexual selection could change some aspects of resemblance. Much information has evolved in this system and could provide opportunities for understanding animal cognition and behaviors. Finally,

Müllerian mimicry in butterflies, first described by Fritz Muller over one hundred years ago, continues to be a system of interest for understanding important aspects of animal cognition and behavior.

## Synonyms

Polygenic effect

## Definition

Polygenic inheritance is described as an inherited characteristic that is governed by more than one gene.

## Mendelian Inheritance

Heritability of human characteristic is often discernible. When we observe a family, we often

notice characters of our parents and grandparents. There are some traits in which one gene controls one character or one phenotype. This is called classical Mendelian trait. However, the mode of inheritance of these traits is not always simple. In fact there are numerous human characteristics whose inheritance is governed by multiple genes also called as multigenic traits. The most classical example of this is height in humans. Height is a trait that is genetically regulated; however we observe many families in which height of the children does not follow height of their parents. Another very example of this is skin color. We often see many families in which skin color of children does not resemble to that of their parents. Remarkably, most of the traits in humans and other organisms are polygenic. These types of non-Mendelian characters are the result of intricate interactions among genes that modify the characteristic of a phenotype.

This is rather interesting to note that these complex gene interactions are observed in diseases as well. It has been observed that a large number of human diseases and disorders are multigenic in nature, that is, a single phenotypic trait is expressed due to mutations in multiple genes. There are basically two classes of trait: monogenic trait and multigenic trait.

### Monogenic Traits

Monogenic traits are characters that are governed by single gene only. For several years, many diseases are known that result from mutation in a particular gene. These diseases are known as monogenic (“single gene”) diseases. The most common example is cystic fibrosis that occurs due to mutation in *CFTR* gene. As monogenic diseases are severe in nature, they are usually rare in population. Selection pressure helps in reducing the prevalence of mutations that are deleterious in nature.

The dominant mutations are effectively eliminated by selection pressure before sexual maturity. However, some monogenic disorders that are caused due to recessive mutations tend to persist in population. Selection pressure acts only of the individuals that are homozygous for those alleles.

In such cases, a reservoir of such genes always persists in the population.

Monogenic disorders are caused due to autosomal genetic mutation. These kinds of mutations can be spontaneous with no family history, or they can follow Mendelian pattern of inheritance also called as Mendelian disorders. The inheritance pattern of Mendelian disorders may be autosomal dominant; autosomal recessive; X-linked dominant; or X-linked recessive. These are described below.

### Autosomal Dominant Inheritance

The term “autosomal” denotes that the gene is present on any of the numbered non-sex chromosomes (Chromosomes 1 through 22). The word “dominant” expresses that even a single copy of the disease-linked mutation will suffice to cause the disease. As this pattern of inheritance involves autosomes only, it effects both males and females equally. The most common examples of this include Huntington’s disease, Ehlers-Danlos syndrome neurofibromatosis, achondroplasia, and Marfan syndrome.

### Autosomal Recessive Inheritance

The term “recessive” refers to alleles which are not expressed in an individual unless an individual inherits both the copies of the mutated gene, one from each parent. Usually, in these cases parents are the carriers of that disease. The most common examples of diseases that follow autosomal recessive mode of inheritance include Huntington’s chorea, polycystic kidney disease, and tuberous sclerosis.

### X-Linked Dominant Inheritance

X-linked dominant inheritance occurs when the gene responsible for the trait is present on the X chromosome. Furthermore, only one copy of the allele is sufficient enough to cause the disease.

Male cells carry one X and one Y chromosome, while female cells consist of two X chromosomes. In X-linked dominant inheritance, a mutation in one copy of an X-linked gene is enough to express the disease. Thus in this condition, both the sexes can be affected, but

males are more severely affected than females. Moreover, in this condition the father is not able to pass on the X-linked dominant condition to the male offspring (due to inheritance of only X chromosome from their mother); however all the daughters will express the disease and will be able to pass on the condition to their children. Some of the examples of diseases that shows X-linked dominant pattern include hypophosphatemic rickets, oral-facial-digital syndrome type I, Rett syndrome, Aicardi syndrome, fragile X syndrome, the X-linked lissencephaly and double-cortex syndrome, and incontinentia pigmenti type 1 (Johnson and Hisama 2007).

### X-Linked Recessive Inheritance

In X-linked recessive inheritance, the males would express the disease phenotype if they inherit the X-linked mutation. Thus, in males, a mutation in the copy X-linked gene can express the disease. However, females must have a mutation on both X chromosomes to express the trait. As sons inherit Y chromosome from their father and daughters inherit X chromosome from their father, affected men will not be able to pass on the trait to their son but to all the daughters. Hence, all their daughters will be the carriers. Some of the most common examples of disorders showing X-linked recessive inheritance are hypohidrotic or anhidrotic ectodermal dysplasia, Duchenne muscular dystrophy (DMD), hemophilia, and Hunter disease. Rarely, female carriers may show mild characteristics of an X-linked disorder. For example, fragile X syndrome.

### Multigenic Traits

In contrast to monogenic traits, the phenotype of multigenic or polygenic traits is regulated by multiple genes present at different loci. This type of genetic defect arises from interaction between multiple genes. Thus, mutation in more than one gene gives rise to multigenic diseases or disorders. It is interesting to note that any one of these mutations alone are not sufficient to cause the disease but together they can result in severe phenotypic changes. These type of genes show

cumulative effect and show a continuous distribution pattern for, e.g., height or skin color. Multigenic inheritance does not follow phenotypic ratios typical to Mendelian inheritance.

The inheritance pattern in which mutation in two different genes results in manifestation of a phenotype is referred to as digenic inheritance. The most common examples of digenic inheritance include retinitis pigmentosa, a disease which occurs due to heterozygous mutation in two genes, viz., *PRPH2* (peripherin-2) and *ROM1* (retinal outer segment membrane protein 1). Notably, mutation in either *PRPH2* or *ROM1* alone is not sufficient enough for manifestation of the disease phenotype (Harel et al. 2015). The following studies established that interaction between proteins encoded by these genes is essential for photoreceptor disk formation (Goldberg and Molday 1996). Interestingly, a more complex digenic model tri-allelic inheritance (resulting from mutation in three alleles, two at one locus and the third at other locus) was evidenced in Bardet-Biedl syndrome (BBS), a genetically heterogeneous ciliopathy that affects many parts of the body. People with this syndrome show primary characters of obesity, visual impairment due to cone-rod dystrophy, extra fingers or toes (polydactyly), hypogonadism, renal malformation, congenital heart disease, and learning difficulties. Mutations in three alleles at two loci are essential to express a BBS phenotype in some familial cases (Katsanis et al. 2001; Eichers et al. 2004; Harel et al. 2015).

When a polygenic trait is subjective to environmental influence, it is called as a multifactorial trait.

Plate L was perhaps the first who used the term “polygenic” (Plate 1932). Later on, Fisher (Fisher 1918) and Mather (Mather 1941) augmented the significance of term “polygenic inheritance” (Guo 2005).

The key characteristics of polygenic inheritance were extensively reviewed by Lerner in 1968 (Lerner 1968). It described the following properties:

1. Multiple genes influence most of the polychotomous traits.
2. Similar phenotypes can be expressed by a great variety of genotypes.

3. Environmental factors are able to considerably influence the phenotypic manifestation of a trait.
4. The genetic pool of the population often contains great reserves of genetic variability.
5. Polygenic traits tend to follow a continuous distribution pattern.
6. The genes regulating polygenic inheritance are no biochemically exceptional.
